Five years do not, it must be admitted, furnish a measure of time on which to predicate maturity, but five years of dermatological work in this day of intellectual activities and scientific appetite, five years of this work done in an association without a predecessor and in the absence of precedent, five years of such work in a country where the special cultivation of the field is of comparatively recent date, this may indeed be a source of profound satisfaction. During these few years of its existence this Association has been in actual session for less than a fortnight altogether, yet the labor which it has stimulated, the influence which it has exerted, and the position which it has attained both in this country and abroad as a body of scientific co-laborers, all these are to be estimated by another standard than that merely of time. Were its work to be concluded with this session, and the last paper to which it should listen be that read on the closing day of this meeting, I should find no fewer reasons for congratulating you on the results accomplished in these five years of labor. No man could sit down to-day to write the history of the progress of medicine in this country for a similar period and omit to mention the contributions to its literature directly and indirectly made under the auspices of this Association. No man could sit down to-day to trace the progress of medical education for a similar period in these United States of America, and be silent upon the increased attention given to the study of cutaneous diseases in our schools of medicine. A large part of this, indeed, is due to the presentation, on the part of this Association, of the claims of such study to a higher recognition, based not merely upon the attractiveness and interest which it always awakens but upon its essential importance.

Five years ago many of our recent graduates in medicine recognized eczema only as a vesicular disease, and their armamentarium for cutaneous maladies was restricted to arsenic for internal use and the benzoated oxide of zinc ointment for topical employment. To-day, many even of our undergraduates who have not yet passed their final examination for a degree, can distinguish between the varieties of lupus, can point out the lesions of pediculi on the skin of the syphilitic patient, and can affirm that this or that eruption is of artificial origin. I do not think that it is claiming too much to hold that for this improvement and promise the influences exerted by this Association are in part responsible.

Reviewing, then, even for this relatively brief period of time, the results actually accomplished by the American Dermatological Association, it occurs to me that we can find reason for congratulation in the following facts:

First. The ground has been occupied. The Association has demonstrated its existence and its capabilities of usefulness to the medical profession of the country. It is here recognized as solely assuming to limit its membership to experts in the field which its occupies; and its proceedings have attracted an attention and been awarded a meed of authority largely proportioned to these conditions.

Second. It has avoided dangers which beset the path of many ventures and experiments. It has assumed no financial obligations which it was not in position to redeem. It was, at the time of its first organization, fortunate in the adoption of a sufficiently simple scheme of self-perpetuation and procedure, in consequence of which it has been enabled to escape the burden of an elaborate and complicated system of rules. It was, moreover, in no haste to enlarge its membership, wisely preferring that its portals should be opened to those only who had previously demonstrated their special fitness for such honor. It has also escaped the dangers incidental to bodies composed of an equally limited number of men acknowledging a community of interests and actuated by similar motives. Its discussions have never lacked virility, and that degree of divergence of opinion and practice which will always characterize the disciples of a true science, so long as there subsists the recognized proportion between the known and the knowable, the attained and the attainable. That upon which we all agree, probably bears an increasing ratio to that upon which we all differ, and with this every scientific association must perforce for the time be content. When the representatives of these bodies are upon all points agreed, then the reasons for their corporate existence are reduced to the level and scope of a mere sentiment.

Third. The transactions of the Association bear witness to the creditable amount and character of the

work performed by its members, both within and without the limits of its sessions. The line of thought in which your attention is thus directed, has been in part suggested by the fact that you are this year to receive the consolidated report of the Chairman of the Committee on Statistics, covering the entire period during which those statistics have been in course of collection. This report will be fitly presented by the first President of the Association, to whose address on the occasion of its first meeting we are indebted for the suggestion, subsequently formally adopted and set in force, relative to the organization of that Committee. This report will inform you that we have collected the statistics relative to no less than sixty thousand cases of cutaneous disease, a larger number than has been heretofore tabulated in any country. The value of these figures, collected as they have been from many and distant parts of the same country, can scarcely be overestimated. It is difficult to believe that the permanent Chairman of this Committee, when his project first assumed definite shape, could have realized how rich would be the results obtained within the time thus far devoted to the work.

We can also refer with satisfaction to the value of the various papers which have been read before the Association, of the cases and specimens which have been exhibited, and of the annual summary of the contributions to dermatology.

Fourth. A final cause for congratulation may be recognized in the fulfilment of the other purposes of the Association, as these are set forth in the address of the first President of the Association, read at our first gathering. These relate to the fostering of an acquaintanceship, to say nothing of the resulting friendship between gentlemen of distant parts of the country, each of whom, however, otherwise made familiar with the special work accomplished by each other, would, without the facilities afforded by the meetings of this Association, be to that extent isolated in his professional labor and interest.

With this fair showing for the past, we naturally turn to the future. It is impossible to doubt that this Association gives a promise of usefulness to its members, and in a scarcely less degree to the medical profession of the country, whose realization will be indeed precious. By pursuing the same straight and simple path which it has heretofore recognized as safest, making sure of its facts and securing the results, with a cool disbelief for that which can not be shown to be worth accepting, it surely needs no great change in either its purpose or policy to reach the desired end.

The President then offered a few suggestions as to the direction and method of further development of the resources and opportunities of the Society, and concluded by expressing the hope that he who shall in five years from this time, pass under review the achievements of this Association during the first decennial of its existence, may find it his agreeable duty to chronicle a proportionately larger measure of good results accomplished, and to point to no less brilliant prospects in the future.

DR. C. HEITZMANN, of New York, then delivered an oral communication entitled,

STUDIES ON MYXO-ANGIOMA OF THE SKIN, CLINICAL AND MICROSCOPICAL.

The peculiar vascular formation sometimes improperly termed *teleangiectasis*, which means simply a dilatation of the vessels, is a very common affection, and may be found on almost any skin. It consists of a new growth of vessels, and is, therefore, a true angioma. It appears in (1) a superficial form, *simple angioma;* (2) invading the glands, *lobular angioma;* (3) entirely subcutaneous, *cavernous angioma*. He confined his remarks to the first form. Microscopically the bloodvessels in this variety were sometimes found imbedded in a homogeneous substance, which it is impossible to define either as myxomatous or sarcomatous, but from other studies he had reached the conclusion that it is really myxomatous, and, therefore, according to the nomenclature of the Association it would be called a myxo-angioma—*myxo* describes the character of the growth, *angioma* indicates the presence of vessels. They vary in size, sometimes are progressive, though they do not generally grow to a great size; at others they remain stationary for an indefinite period. Hardly raised above the skin usually, they yet may appear as lentil or pea-shaped excrescences; they are readily recognized by their red color which can be made to fade on pressure; it is generally of a dark hue. They occasionally ulcerate, and sometimes bleed. They may be successfully extirpated in two ways; if pedunculated, they may be cut off with the scissors, and the next moment applying a stick of nitrate of silver, or smoking nitric acid to the spot; if they are sessile, the smoking nitric acid should be applied directly. He had used the galvano-cautery only to a slight extent, but his experience with electrolysis in epilation had taught him that this method might also be useful in the treatment of angiomata.

As regards etiology, he was unable to give any explanation of the cause of the myxomatous degeneration or of the increase of the bloodvessels, but from careful observation he was able to describe how the new formation occurred, the new vessels budding out from the walls of the old; at first they are solid, and afterwards become tubular.

Dr. J. NEVINS HYDE, of Chicago, read a paper on

DERMATITIS PAPILLARIS CAPILITII.

This he described to be a localized inflammation of the deeper structures of the skin, occurring in patches on the nucha, especially beginning at the junction of the hairy scalp with the neck. The patches were not uniform in size, but varied up to the size of the palm of the hand. The border of the *plaque* is usually irregular, and is sharply defined, the whole *lesion* being elevated more or less. The surface was not pigmented, nor otherwise affected. In shape the patches were irregularly roundish. Upon making a small opening in the centre of the lesion, a considerable quantity of pus exuded, followed by thin mucus-like fluid tinged with blood. By pressure the subcutaneous cavity which evidently existed, would slowly empty through the puncture, and when pressure was removed, the cavity would gradually fill with the bloody fluid referred to, which could again be forced out by pressure. This manipulation could be repeated several times. The fluid was suggestive of that recognized in the form of ringworm known as *kerion*, but no parasite was present, and the lecturer was disposed to regard the affection as an inflammation of the deeper structure of the skin of the hairy scalp, which assumed at its commencement the papular form.

At the EVENING SESSION, DR. ROBERT W. TAYLOR, of New York, read some

NOTES ON PSORIASIS.

After calling attention to a view concerning the pathology of psoriasis expressed by Erasmus Wilson, that it was a remote outbreak of syphilis after transmission through several generations, he said that he had been interested in investigating the possible relationship, and had made a practice for several years of interrogating patients closely as to the existence of syphilis in the family. Further observation had impressed upon him that, in fully twenty-five per cent. of his cases, he could obtain a history of syphilis in one or both parents. In none of these was the specific disease in an active stage.

In one, syphilis had occurred fifteen years before, and in another the last outbreak had appeared fully three years prior to the birth of the child affected with psoriasis. In all the cases the psoriatic children had been the later ones; in one instance the sister had notched teeth and other evidences of syphilis, but the brother born afterward was afflicted with psoriasis. Usually psoriasis shows itself before puberty, he had seen it as early as the second year, and in most cases the first manifestation occurs in the early years; it is a disease incidental to the developmental period of human life. Certain cases of papular syphilis show some resemblance to psoriasis that are perplexing, it is also like it in the inveterateness of the disorder.

As Hebra has taught, the prognosis of psoriasis is usually bad, still it may be cured, if treated early, in a great many cases. In young subjects the combination of arsenic and mercury known as Donovan's solution had proved very efficient in his hands. After the disease has existed for a long time and impressed the pathological tendency upon the skin, it becomes much more difficult to overcome.

DR. ROHÉ, of Baltimore, read a report of

TWO CASES OF ACUTE GENERAL PSORIASIS FOLLOWING VACCINATION.

The first case was that of a physician, aged twenty-eight, who had never suffered from any skin affection, rheumatism, gout, or syphilis. Neither had any of the recognized manifestations of these disorders appeared in any member of the patient's family.

About ten days after an unsuccessful vaccination with bovine virus in last January the punctured spot became scaly and very itchy and reddened. In the course of the following two weeks the entire body, except the palms of the hands and soles of the feet became covered with small, scaly, red papules, which rapidly enlarged. The eruption was more thickly aggregated on the extensor surfaces of the arms, the thighs, and trunk. The itching was very intense, interfering seriously with the rest and nutrition of the patient. The diagnosis of acute general psoriasis was made after a few days' observation of the case.

Under arsenic the trouble grew worse, the irritation increasing considerably. The arsenic was stopped and acetate of potash in half-drachm doses, with half a drachm of fluid extract of taraxacum, was ordered thrice daily, with a daily hot bath rendered alkaline with carbonate of sodium. In three weeks after the beginning of the alkaline treatment the eruption had entirely disappeared. The spots retained the characteristic dark-colored pigmentation of psoriatic *plaques* for some time after the production of scales and the infiltration of the skin had disappeared.

The second case was that of a nine-year old boy who, several weeks after a successful vaccination with bovine virus, developed an attack of general psoriasis, which yielded to the administration of Fowler's solution in three-drop doses.

Dr. Rohé stated that he had not been able to find in the literature any mention of the connection of psoriasis with vaccination.

CALX SULPHURATA.

In a short communication, Dr. H. G. PIFFARD referred to the observation of Ringer, concerning the use of sulphide of calcium in acne, and said that he could confirm it from his own experience. There is great variation in the composition of the salt as dispensed by druggists, some of it being nearly free from sulphur, and one specimen he had examined contained no sulphide of calcium whatever. At best, its composition is not uniform, and therefore the new pharmacopœia would consider it under the title of "sulphurated lime." Pure calcium sulphide is a pharmaceutical curiosity, and would be much more expensive.

He attributed the reported failures from the use of this drug to the defective composition, and to the habit of increasing the dose. It should be given ordinarily in doses of gr. $\frac{1}{10}$ to $\frac{1}{4}$, and rarely as high as one grain. In acne, the amount should vary with the grade of the disease; the more acute it is, the smaller should be the dose; with it he sometimes uses locally a dusting powder of sulphur.

He had also used the calx sulphurata successfully, in the eczema of children, and in the eczema of the chin in the male, the non-specific sycosis of some authors; in the latter he also pulls out such hairs as emerge from pustules, and had seen very good results in cases that had resisted the local treatment alone.

In a case of diabetes, he had noticed that the sugar had disappeared while the patient was taken this drug, and two cases of swelling of the lip had yielded promptly after a few doses had been taken.

AUGUST 3D.—SECOND DAY'S SESSION.

DR. WM. A. HARDAWAY, of St. Louis, reported

A CASE OF PIGMENTED NEOPLASM OF THE SKIN.

A merchant, 40 years of age, without skin disease in his family previously, presented himself for treatment with a number of deeply pigmented spots on his face. Although he had a history of gonorrhœa, and vegetations behind the glans penis, he denied symptoms of syphilis; never had sore throat, skin eruption, falling out of hair, etc. He was married in 1878, and had two healthy children. He had varioloid in 1868; he had a discharge from the ear since childhood. He noticed a number of enlarged glands in various situations, notably in the axilla, neck, groin, and elbow, on both sides, about 1871, when he had the vegetations already noticed. To rid himself of these, he took iodide of potassium, on his own responsibility, for several months. About three months later he stopped it because papules appeared on his face, which, as they subsided, left dark pigmented spots. Subsequently, spots came without being preceded by papules, and slowly increased in size. Vigorous anti-syphilitic treatment by another practitioner produced no effect on glands or spots.

An oil painting of the case was submitted with the paper. The skin, except in the parts occupied by the patches, is perfectly normal. Besides those on the face and neck, other spots exist upon the knees and insteps. They vary from the size of a split pea up to one 2 inches by 1 inch in width, the large ones being on the neck. The general shape of the patches was oval. The centre of the lesions was pinkish, but the borders were decidedly orange-hued, the small ones were all orange-colored. The centre of large patches is traversed by vessels which do not run into the border, the small ones do not show these vessels. The border of large spots, and the surface of small ones is slightly cracked and frayed, but the large centres have a smooth epidermic covering. The orange-colored border, about $\frac{1}{8}$ inch in width, was slightly elevated, centres somewhat depressed. The smaller ones are slightly raised. Upon pinching up the neoplasm it was found that the skin was slightly infiltrated, but the patches were freely movable. The large patches on forehead appeared to be undergoing involution at the centre. There was no difference in sensibility in the patches, and perspiration was not absent. A piece of the largest patch was excised for microscopic examination, and sent to Dr. Heitzmann. The wound was united by sutures, and healed by first intention.

Dr. Heitzmann reported that the growth had the characters of a *myeloma* or pigmented medullary sarcoma of the skin.

THE NERVES OF THE SKIN.

A valuable contribution to the histology of the skin and the sensory nerves was read by DR. A. R. ROBINSON, of New York, in a contribution based upon original microscopical study of the structures named; it was accompanied by some beautiful sections for exhibition with the microscope.

In this paper the author discussed the course and mode of termination of the medullated and non-medullated nerves present in the skin. The non-medullated, he stated, form plexuses both within the skin and epidermis; but in neither situation did he find the nerves ending with free extremities, as is usually stated. The majority of the medullated fibres pass into the papillæ and form loops, the fibres returning either into the corium or into neighboring papillæ.

He described the structure of the tactile corpuscles, showing that the striated appearance depends upon nerve fibres and upon the neurilemma. This was proven by the action of a weak solution of caustic potash upon gold specimens. He reviewed the evidence in favor of the corpuscle being a structure within which the nerve fibres terminate; denying its correctness, and maintaining that the corpuscle represents only a nerve plexus, basing his view upon the following grounds:

1. Medullated nerve fibres not connected with tactile or Pacchionian corpuscles, form loops within the papillæ, and return to the corium or neighboring papillæ.

2. Non-medullated nerve fibres form loops and plexuses within the papillæ and epidermis, and probably do not terminate by free extremities.

3. In the majority of tactile corpuscles two nerves can be observed to be in connection with it, the one at the base and the other generally at the upper part.

4. Instead of a single medullated fibre at the upper part there is sometimes two medullated, or two or more non-medullated.

5. That the nerve entering at the base can often be seen winding upward toward the apex and forming the transverse striæ, which color in gold.

6. That the nerve within the corpuscle generally retains more or less of its medullary sheath, and rarely divides in this situation.

7. The complete absence in many corpuscles of any irregularity of contour of the fibre; hence absence of any structure resembling the end-buds of Langerhaus.

8. The nerve fibre in connection with the corpuscle at the upper part can be seen to be in connection with the transverse nerve striæ which appear to come from the winding upward of the afferent nerve.

Thirty-six wood engravings accompany the paper.

THE QUESTION OF THE CONTAGION OF LEPROSY.

In a very elaborate communication (which will appear in full in the October issue of the *American Journal of the Medical Sciences*) Dr. JAMES P. WHITE, of Boston, discussed the question of the contagiousness of leprosy. He regards the term "sporadic leprosy" with great distrust, since on account of the chronic character of the disease and the want of control over patients afflicted with it, it is impossible to say that a case might not have been communicated by contagion from some other. There are an unknown number of lepers in the United States, existing as widely separated as San Francisco, New Orleans, and New York. There is also a settlement at Cape Breton in Canada. He regarded the whole subject as one worthy of the attention of the General Government and the National Board of Health, in view of the facts showing that the disease is communicable from the sick to the well, and practically incurable.

THE USE OF ERGOT IN SKIN DISEASES.

Dr. C. HEITZMAN, of New York, made some remarks on the use of ergot in different forms of skin disease. His attention had been called to it by a paper written some years ago by Dr. Le Grande Denslow. He used it locally and internally, and had found it of great service in many forms of skin disease unattended by marked structural changes except of a congestive character. In pruritus it had, in several cases, acted like a charm. In certain forms of acne, especially the large pustular form in the beard, it is very useful, and also in both forms of erythema, especially where there is dilatation or new formation of vessels. In a few cases of eczema and in psoriasis it was less effective.

He used Squibb's fluid extract in half drachm doses usually.

DR. J. E. ATKINSON, of Baltimore, read a paper on

SYPHILODERMA PAPULOSUM CIRCINATUM, A RARE FORM OF SYPHILITIC MANIFESTATION.

He said: Although all syphilographers describe the large, flat, papular syphiloderm, together with many of its peculiarities, sufficient attention has but seldom been given to a form of eruption that always has this syphiloderm as a starting-point. This may be, with propriety, designated as the circinate papular syphiloderm. Its claim to special attention consists in its tendency to develop out of the large, flat, papular eruption by a depression in its centre and a peripheral extension of its limits. In the course of this centrifugal growth, the depressed central portion returns to the normal limits of elevation of the skin, while the raised margin forms a narrow, sharply defined, continuous, encircling boundary, whose surface becomes the seat of a rather scanty desquamation. Occasionally, when the desquamation is very copious, the epidermis may be thrown off down to the very lowest layers of the rete mucosum, and the surface of the lesion will then be moist, lightly exuding, and shortly afterward a thin, serous or brownish crust is formed, which soon dries and falls off, leaving a pigmented surface that slowly returns to its natural condition. With the unelevated centre and the narrow circumscribing border, the lesion may attain the size even of a half-dollar, and altogether loose all resemblance to a papular eruption, more nearly resembling severe tinea circinata. The eruption is sometimes accompanied by itching. The patch by irregular extension slowly becomes less circular in outline, and when several coalesce, curious figures are formed. This eruption belongs to the secondary period of syphilis, from about the third month to the eighteenth month; it affects both sexes, and is frequently located on the back, breast, head, neck, and extremities, though in mild cases a few circles upon the face may represent the entire eruption. A history of syphilitic infection will usually dispel doubt as to the nature of the eruption, the clinical characters of which resemble those of tinea circinata, psoriasis, erythema multiforme, and the late tertiary papulo-tubercular and tubercular eruptions; from the latter it differs in always starting from a single lesion, while the circular patches of late syphilis represent the peculiar tendency of the disease to group its lesions in a definite manner.

REPORT OF THE COMMITTEE ON STATISTICS.

DR. JAS. C. WHITE, Chairman of the Committee on Statistics, presented a carefully elaborated report in which the statistics of the Association for the last five years were communicated, giving a total of 58,617 cases of cutaneous disease. The report received from the different districts represented in the Society, Boston, New York, Philadelphia, Baltimore, St. Louis, and Canada, showed a total of 11,514 cases observed during the last year by competent men, among these were: eczema 3241, urticaria 347, pityriasis rubra 8 (all from New York); lichen 39, purigo 2, acne 664, impetigo 95, pemphigus 21, purpura hemorrhagica 39, purpura sim-

plex 8, syphilodermata 1544, pruritus 212, scabies 247, lepra anæsthetica 1, etc.

There being no discussion upon this report DR. WHITE then related

AN EXPERIENCE IN SKIN DISEASE.

After treating a case of warts upon the hands for some time, he was induced to try a combination of salicylic acid, cannabis Indica, and collodion, which was very successful. He had used it several times since with equally good results. The proportions were about ten grains of the extract of cannabis Indica, and thirty grains of the acid, to an ounce of collodion. In fifty cases he had never seen it fail; it should be applied daily for three or four days.

DR. HARDAWAY recommended electrolysis, which he uses with good results, piercing the base of the papillary growth with a needle.

A CASE OF PELLAGRA.

DR. SHERWOOD forwarded a communication to the Society detailing the clinical history of a case of *pellagra* in an Italian sailor treated at the Long Island College Hospital. The eruption was of an erythematous appearance, and came out first on the forehead and extended over the face, hands, and body, and was accompanied by suppurating cervical glands and great depression of spirits. The temperature at times went as high as 105½°. The case is still under treatment.

SEPTEMBER IST.—THIRD DAY.

The closing session was devoted to the examination of a number of microscopic preparations exhibited by Dr. C. Heitzman and by Dr. A. Robinson.

At the business session three new members were elected, Dr. H.W. Stellwagen, of Philadelphia, and Drs. P. A. Morgan and W. T. Alexander, of New York City.

The nominating committee presented its report, and the following were unanimously elected

OFFICERS FOR THE ENSUING YEAR:

President, R. W. TAYLOR, M.D., of New York.

Vice-Presidents, I. E. ATKINSON, M. D., of Baltimore, and A. R. ROBINSON, M.D., of New York.

Secretary, A. VAN HARLINGEN, M.D., of Philadelphia.

Treasurer, GEORGE H. ROHÉ, M.D., of Baltimore.

It was decided to hold the next annual meeting at *Lake George* on the Wednesday nearest the first of September and the two following days.

The Association then adjourned.

CORRESPONDENCE.

STUDIES AND EXPERIMENTS WITH SEPTICÆMIA IN THE LABORATORY AT BERLIN.

PARIS, August 18, 1882.

WHOEVER would imagine for a moment that the subject of tuberculosis, wide as it is, was the only one pursued at the mycological laboratory at Berlin, would make a very great mistake. The truth is, the discovery of the bacillus tuberculosis was only the crown and culmination—and a fitting one it was—to a long series of investigations in a very much wider field. Some of these investigations, as those connected with milzbrand, having led to the most important conclusions, are well and widely known, but there are many others, some settled, some still in prosecution, the results of which have not yet received the dissemination to which they are entitled. Some of them were published last year in great detail in the *Mittheilungen aus dem Kaiserlichen Gesundheits-Amt*, by the director Dr. Struck, a volume which every worker with micro-organisms should possess and thoroughly peruse, and some have been published in the various medical journals; but very few, if all of them, have received that degree of recognition with us, at least, which their value demands in view of the recent discoveries. I may be excused, therefore, for attempting to finish from my notes the report begun in my last of some other studies allied to, but in a sense alien from, the question of tuberculosis. It is my humble opinion that considerable time will elapse before we shall have any very important additional contributions to the subject of tuberculosis, for it appears to me that Koch has done his work about as Harvey did his before him, in such a way, that is, as not to have left very much room for subsequent disclosures. Harvey took twenty years, by the way, and Koch two, which is about the equivalent in our times, after making his discovery, before he published it at all, so that there is as little fear on the part of those few who are competent to give an opinion of any refutation of his views. It is amusing to read the comments in this direction, I may put it here in parenthesis, by the *litterateurs* in our profession, which are about as destructive to the peace of mind of the workers in the laboratory as the presence would be of a man in the street outside who was posing himself before the public and diverting them by balancing long straws across the bridge of his nose.

But neither their comments nor my criticism savor of science in the least, and I proceed with my report, in which I propose to confine myself simply to a narration of experiments which were made before my eyes, and some of which I was kindly permitted to repeat myself.

And first, of septicæmia, which ranks in practical interest only next to tuberculosis. It was contended by Darwin that this condition could be superinduced in more and more virulent form with every re-inoculation, that is, that less and less infecting material needed to be used to produce the same results by inoculating from animals successively killed. This view seemed to be in accord with, or in support of, a doctrine published by Nägeli, to the effect that bacteria could be changed from one form to another by changing their surrounding media, and was hailed with delight by the supporters of Weymuth, who maintained that the innocent bacteria found in such numbers in feces could, under certain circumstances, be endowed with such properties as to produce various diseases, as typhus or typhoid fevers. Buchner's claims, too, of the transformation of the innocent bacillus of hay into the malignant bacillus of anthrax was in accord with this view. Now the teaching of the Koch school is diametrically opposed to any such mutability. That is, it is not contended that any transformation is impossible, because, as I have said before, nothing is accepted here on mere theoretical grounds, but it is proven of these particular forms that no such change does occur, and that the erroneous conclusion is due to impurification (*verunreinigung*) in the experiment. When the proper precautions are taken in the process of sterilization to prevent the possible admixture of other micro-organisms, the introduction of one kind always produces in the same animal the same results. So far as the conclusions of Darwin are concerned, there is only one virulent result, and that is death, and this result is obtained whether there is introduced a whole drop containing the micro-organisms or only the infinitesimal fraction of a drop. Full evidence is manifested in one or two generations, and later cultivations do not increase it.

The most interesting conclusions to be drawn from the experiments in Berlin point to the fact that "septicæmia" is only a general term which includes a whole array of morbid processes, and this is very well illustrated by the injection into the subcutaneous tissue

of the so-called "*vibriones septiques*" of Pasteur. Here it has been found that these bacilli, to produce their effects, must be introduced below the whole depth of the skin, that is, by hypodermic injections, and that inoculation or surface abrasion will rarely suffice. The effect, then, is first, an œdematous infiltration of the tissue at the point of injection, and an extension of the inflammation from this point to the deeper structures. The blood of the heart, for instance, does not contain these bacilli at first, unless accidentally admitted in the examination of it, but later, some time after the death of the animal, abounds in them. Here then is a bacillus which, so far from being killed by decomposition, actually increases under it for a time, a bacillus which is entirely different from the common bacterium of decomposition. Koch has given the name of "malignant œdema" to this condition, a term which describes its character much better than septicæmia. Gaffky, one of the best of the *mitarbeiters* at the laboratory, after many futile trials, at last discovered that the inside of a cooked potato was about the best culture soil for this bacillus, which readily grows in it, and thus offers a depot whence to extract it for further experimentation.

A particle taken from a second potato, that is a second generation, introduced under the skin of guinea-pig, kills it on the next day with all the customary signs of malignant œdema. This bacillus abounds in the soil, and is derived at any time from the earth of the garden.

Thus different and highly distinct forms of micro-organisms are now in the laboratory ready for use at any time, the inoculation of any of which will produce a form or variety of septicæmia. One is that of the malignant œdema just described, one is the most extremely fine bacillus, the finest of all hitherto described, which Koch worked out in his experiments with "*wundinfection*," called the "mouse septicæmia," and the third is the large oval micrococcus, called the "rabbit septicæmia;" either of these latter two being transmissible to either animal, and to many others.

After very many experiments the proper culture substance has been found for each of them, and continued generators are constantly kept on hand in the sterilized test-tubes so often mentioned. It is easy to see that these forms, at least, do not undergo any change whatever, and that when apparent changes occur, the phenomena is due to admixture of other forms, in other words, to an impurification. After hundreds of observations, with the avoidance of every possible source of error, Gaffky came to the conclusion that the "pathogenic micro-organisms, which were the subject of study, are produced only by themselves and only produce themselves."

It was only by means of the solid culture substance that pure so-called central observations could be made. A fragment is picked up from the surface of the gelatine slide from time to time and examined under the microscope, when any admixture of foreign micro-organisms is seen at once. Just so soon as the introduction into an animal of a fragment of gelatine thus used as a culture substance fails to give the expected result, it is known that an impurification has nevertheless occurred, and the simplest examination by the microscope reveals the cause of the failure at once.

I have already intimated that very various kinds of culture substances are in use. What is a favorable soil for one is not necessarily a favorable soil for another micro-organism. Indeed, some varieties become sterile in certain soils and die out, and there is no knowing in any way what is the best soil except by experiment. For this extremely minute bacillus of the "mouse septicæmia," for instance, Koch tried various culture soils, and at last found that he could grow it in a composition of gelatine with the aqueous humor of the eye of the ox. But the growth was very feeble, and successive inoculations or cultivations upon new beds of the same soil uncertain. Finally, Löffler, another skilful mitarbeiter worked up a composition of infusion of meal with peptone one per ct., and common salt 0.6 per ct., the whole rendered very faintly alkaline with sodium phosphate, which was a most luxuriant culture substance for the *Mäuscher septicæmia*. It is perfectly clear and transparent, and the bacilli develop in it in colonies visible as opacities upon its surface. Generations of these bacilli have been grown in this soil now for nearly two years, and the growth is as fresh and virulent as ever. Two days before I left Berlin I took my first lesson with this bacillus. I was instructed to fix the mouse, as I have described before, in a glass jar, to draw out the tail, to clip off a few hairs at its root, to make a minute incision, a little skin pocket, and to introduce into it by means of the platinum point previously *ausgeglüht*, a minimal, scarcely perceptible, quantity of the gelatine, all of which was done, when I was informed that the mouse would die, with mathematical certainty, in from forty to seventy-two hours, and so it did in forty-eight. A mouse ill with septicæmia acts very much like a man under the same affliction.

Another experiment was to produce erysipelas in the ears of a rabbit by the introduction of this same bacillus into a skin pocket on the inner surface of one ear. The redness begins on the first day, increases on the second, with swelling and opacity to light, when the ear falls by its own weight, and makes a striking contrast with the sound ear. On the third day the erysipelas reaches the base of the ear, on the fourth it begins to invade the sound ear, subsiding already in the affected ear, and in the course of a week or ten days is followed by a distinct desquamation, just as is seen in ordinary erysipelas. But the ordinary erysipelas of man is not due to this bacillus. The cause of ordinary erysipelas is not a bacillus at all, but a micrococcus which has also been thoroughly worked out, and is handsomely pictured in the photographic tables of the "*Mittheilungen*." But I may not take up too much space with the narration of known facts, as the only excuse I have for writing so much away from the field is the fact that the sounds of the fight, if I may use so noisy a word in description of such quiet work, keeps still ringing in my ears.

Whatever I have written, anyhow, has been rather with a view to secure credence and recognition in my country for work which when published only in its results seems to many too strange to be true. There are those with us who are thoroughly prepared for these results; who have followed up the links for the last twenty years, beginning, I may say, with Villemin, from obscurity into light. To them there is nothing strange or new in all that I have said. But there are also many others who have looked upon these labors with an air of incredulity rather than credence from the start, and have, hence, not taken time to trace up the steps which gradually led to the main disclosures. To them the results are something like a shock; and it is only by acquaintance with the methods of work, with the patient, persistent—I had almost said painful—processes which have been going on for years that the results reached at last can be believed to be true. They have the right view in the opinion of the real connoisseurs over here, who look upon them as constituting the most brilliant contribution in the history of medicine since the day of the discovery of the circulation of the blood.

J. T. W.

THE GUITEAU AUTOPSY.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: Advantage is taken of the publication of the reports of the microscopical examination of the brain, and of the measurements of the skull of Guiteau,

to reply to some strictures which have been made upon the official report of the autopsy.

1. The omission therefrom of the very important matter of these measurements has been regarded as inexcusable; they were not taken, however, until after the skull had been cleaned, too late to appear in the report. The greater accuracy secured in this way justified the postponement.

2. The statement in the report that "there was a slight flattened elevation of the corresponding internal surface of the calvaria," denied by some, has since been repeatedly verified.

3. It has been stated that the brain would have been found to weigh more than was reported, had the scales been more delicate. The scales used weighed to the half ounce; as far as known, no objection was made at the time to the weight as taken; had there been, there were scales of unquestionable accuracy accessible within the hour.

4. It has been objected that the section of the great bloodvessels of the thorax before the removal of the brain was the cause of the anæmia of the latter. The conclusion is a *non sequitur*.

To save time (a very important point in the Guiteau autopsy), it is the habit of some, myself among the number, to open and examine, as far as possible, the cavities of the trunk, while an assistant is doing the rather tedious work of opening the skull. Experience has shown that such a procedure is not necessarily followed by anæmia of the brain; on the contrary, congestion is often found. There are many such instances recorded in my notes.

Virchow, than whom there is no higher authority, reports, in his work on post-mortem examinations, the details of four medico-legal cases. In two of the four he examined the thorax and abdomen before opening the head. In one of these (translation by Dr. Smith, 1880, p. 99 *et seq.*), he found the dura mater copiously supplied with blood, the veins of the pia mater very large and much distended with dark blood, on section of the hemispheres the veins were much distended, and large drops of blood exuded from the cut surface; the cerebellum presented a similar appearance, the arteries at the base of the brain and sinuses at the base of the skull were full of dark blood. The adjectives are his own. In the second case (p. 103) fluid blood was found in the heart and large vessels of the thorax and neck; yet, on opening the head, fluid blood also was found in the longitudinal sinus, the pia mater showed venous networks everywhere, and the choroid plexus was congested. The hemispheres, however, were "remarkably pale." He does not explain this paleness on the theory of drainage, but (p. 115) considers it of pathological importance.

Wilks and Moxon, in their *Pathological Anatomy* (1875, p. 202), admit that though the head may be opened after the examination of the trunk cavities, the brain and membranes may be found "very full of blood," even though the person may have been dead only a short time. They add, in italics, the accepted opinion, that the fulness of the vessels of the brain is of no pathological significance whatever, so far as disease of the brain is concerned.

That in the Guiteau brain, the anæmia may have been partly due to drainage, is not denied; but such drainage probably took place, if at all, mainly during the three to four hours interval between the removal of the brain from the skull and the incision into it. In this connection, the hypostatic fulness of the vessels of the pia mater noted in the report may be recalled.

5. It has been further objected that the drainage of the brain diminished its proper weight. The highest authority in the weighing of the human brain is probably Broca. In his *Instructions Générales*, etc. (Paris, 1879, p. 18), he directs that after removing the brain it should be carefully placed upon a table for a short time so that the excess of fluids may run off. After it has been sufficiently drained (*convenablement égoutté*), it should be weighed.

It may be added that the circumstances under which the autopsy and report were made, will explain some omissions and commissions which were not *en regle*.

Truly yours,

D. S. LAMB.

ARMY MEDICAL MUSEUM, WASHINGTON,

VIENNA.

(*From our Special Correspondent.*)

OBSTETRICAL OPERATIVE INSTITUTE OF THE VIENNA MEDICAL FACULTY.—The creation of an operative school in obstetrics, for the exclusive benefit of Austrian practitioners of medicine, must be of great interest to all physicians.

For a long number of years, the resident physicians of the three large hospitals of Vienna have been petitioning the ministry of education for means to gain practical knowledge of obstetrics. They claimed that the colossal material was utilized by Americans, Englishmen, Russians, and foreigners generally, while native students were treated, for pecuniary reasons, with marked injustice. In 1879, a very spirited remonstrance was made, and petitions were forwarded to the Royal and Imperial Ministry of Education.

After an interval of almost three years, the ministry has established the following provisional statute:

"With the 1st September, 1882, an Obstetrical Operative Institute, in the Medical Faculty of the University of Vienna, will enter upon existence, whose provisional statutes, approved by the ministry of education, and designed for acquiring knowledge and instruction, are the following:

1. The object of the institute is the cultivation of a larger number of experienced obstetricians.

2. The conductors of the institute are the three Professors of Obstetrics in the University of Vienna.

3. Every native of the lands, represented in the Reichsrath, is entitled to entrance into the institute upon the exhibition of his acquired diploma in medicine surgery, and obstetrics.

4. The length of the course is six months; the first course begins upon September 1st, and ends upon the last day of February; the second begins with the 1st of March, and ends upon the last of August. Under exceptional circumstances, the time of work can be extended to the attendant physicians for one year.

5. In every course, according to the rule, only nine attendant physicians will be accepted. Of these, three will be appointed to each clinic. The appointment of more than four attendants to each clinic is not allowable.

6. Hospital physicians, still serving, or just going out of service, must announce their candidacy to the hospital director concerned, who will forward the applications to the college of professors. Applicants, who stood in no service-relation to a hospital, will announce their candidacy with evidence of former employment, directly to the 'Decanat.'

7. The college of professors will decide upon all appointments, yet they must prefer, before all others, the competing hospital physicians.

8. The attendant physicians will be subordinate to the professors and their proxies; will have, in the clinics, subordinate service under supervision of the professor, especially inspection; are entitled, in addition, to assist

at all operations, and according to their proficiency, will be allowed to undertake obstetric operations, in viva, under the supervision of the professors or their proxies. In order to carry this plan out, instruction, at the beginning of each course, will be given to the attendants.

9. After completion of the course, the attendant physicians, upon desire, can obtain a certificate, written by the professor, and certified by the Decanat."

The appearance of this statute has given rise to the liveliest comment in Vienna medical circles. The native physicians are delighted with their partial victory; the assistants, who have reaped a golden harvest at the hands of foreigners, chiefly Americans, are highly incensed at the prospect of loss of the large sums foreign physicians leave in their possession; the Americans, Englishmen, Germans, Russians, and Greeks, are completing their courses with regret. Notwithstanding the enormous number of births occurring yearly in the "Allgemeine Krankenhaus," numbering more than 10,000, the number of students from every section of the globe is proportionate; although the obstetrical institute is only a provisional arrangement, it would be well for men, seeking training in obstetrics and gynecology, to think well before coming to Vienna for the ensuing winter.

Yellow Fever.—The yellow fever news from Brownsville, Texas, during the week, has consisted of bulletins indicating the daily occurrence of from fifty to one hundred cases with comparatively few deaths. The relative mortality indicates the disease as of an exceptionally mild type, or, which is presumably the correct view, that all cases of fever, including the autumnal remittents prevalent in that locality, are included in the reports. Everything is being done by the general government, through the agency of the Marine-Hospital Service, to care for the sick and prevent the spread of the disease. Hospitals have been established by Surgeon Murray of that service, and a sanitary cordon has been drawn across the country from Laredo to Corpus Christi, to prevent the escape of fugitives from the infected district. The country is said to be low, sandy, free from timber, and easily guarded.

The invasion of Brownsville from Mexico is well established, but the origin of the disease in Pensacola appears enveloped in obscurity. During the summer several infected vessels were sent from the quarantine at this port to Ship Island Refuge Station. Two Italian barques arrived recently, each having three cases on board; but the origin of the excitement—although probably not of the disease—among the people was the occurrence of a death and two cases of sickness on board a Spanish ship, the "Saleta," on the 10th of August. The fatal case was seen by a medical man an hour or two before the patient died. The doctor was not positive in his diagnosis, but as a precautionary measure the Saleta was towed to sea within a few hours. Dr. Carrington, in the Pensacola *Advance-Gazette*, gave the sanitary history of the Saleta showing that forty-five days had elapsed since she left an infected port, and that in the meantime she had been unloaded and fumigated. Dr. Jerome Cochran, of Alabama, made an official investigation into the condition of Pensacola, reviewed the Saleta affair, and concluded that there were no just grounds for alarm. But some days afterwards (August 28th), the City Board made formal announcement of the existence of yellow fever. This created considerable alarm in the neighboring cities. The Louisiana State Board prohibited the railway company from running trains from the infected city within the boundary of their State. Montgomery and Mobile are also stated to have quarantined against Pensacola.

When one considers the thousands who suffered by the introduction of a single case into New Orleans in 1878, the action of the Louisiana State Board is manifestly justifiable in default of provision for preventing the spread of the disease during commercial intercourse, but experience gathered since then has shown that safety may be attained without a recourse to non-intercourse. Recently when three or four cases existed in New Orleans the health authorities of Mississippi, instead of quarantining against the city, permitted free intercourse under the inspection system of the National Board of Health.

We have not heard that any call has been made on the National Board by State or local boards to assume control of the passenger and other traffic between Pensacola and its neighbors on the lines of rail, but this is no doubt because the commercial interests involved are so small as compared with those of New Orleans.

The able and energetic Health Officer of Pensacola, Dr. J. C. Whiting, took immediate steps to localize and stamp out the disease and to prevent panic. His latest telegram, dated September 3d, shows what success has so far attended his efforts: "No new cases of fever in the past two days. One death Friday. Have had in all nineteen cases and five deaths. Seven sick now, two of whom will likely die; others improving. No fever in shipping or in quarantine. Total mortality for the week, seven—five from yellow fever. No excitement and people very hopeful." We shall look with much interest for the ultimate results of the operations of the Pensacola City Board.

National Medical and Sanitary Exhibition.—A convention of Commissioners appointed by the National and various State Boards of Health of the United States, together with Commissioners appointed by the American Public Health Association, will assemble at Indianapolis, Ind., on Wednesday, October 18, 1882, at 9 o'clock A.M., to take into consideration the question as to the best course to be pursued which may result in holding a National Medical and Sanitary Exhibition in the year 1883.

Additional Honor to Prof. Langenbeck.—Prof. Langenbeck has received from his government the highest attainable distinction, in being designated as Active Privy Councillor, with the prefix "Excellency." On his departure from Berlin he will receive a handsomely engrossed address on the part of the medical students.

Prof. Graham Bell, the inventor of the telephone, received the honorary degree of Doctor of Medicine, at the Tercenary Celebration of the University of Würzburg.

Professor Esmarch on the Case of President Garfield.—Prof. Esmarch delivered a lecture on the treatment of President Garfield's wound before the Physiological Society of Kiel, in February last. This lecture he has now printed and circulated, and it is impossible that the views of a surgeon so accomplished and so worthy of expressing an opinion on such a case should not be canvassed. The facts of the case are first of all clearly and fairly stated from Dr. Bliss's own published accounts of the progress of the case and of the post-mortem examination. Prof. Esmarch's conclusions are (1) that the wound was not in itself absolutely fatal; (2) that the bullet was not the cause of the septic suppuration in the wound which led to the fatal result; (3) that the cause of the septic suppuration was introduced from without, and that as contributing directly or indirectly to this were the following

errors in the treatment—the repeated probing and examination of the wound with instruments and fingers not rendered aseptic, the failure to dress the wound aseptically, the syringing out of the wound with fluids not sufficiently antiseptic, and a failure to give a complete vent to the "bagging" pus; (4) there was no true pyæmia, but only metastatic inflammation of the parotid gland; (5) the cause of death was hemorrhage, moderate in amount, but occurring in one whose strength was undermined by septic fever, decubitus, bronchial catarrh, and hypostatic pneumonia; (6) although the splenic artery may have been injured primarily by the bullet, or by a splinter of bone, this would not have led to the formation of a false aneurism except for the establishment of putrid suppuration. In conclusion, Prof. Esmarch refers to the popular superstition that the bullet is the cause of all danger in a gunshot wound, and that to extract the bullet should be the chief aim of the surgeon. He asserts that most of the secondary dangers arise rather from the fingers of those who explore the wound, and that the American surgeons committed the error of doing too much rather than of doing too little, as they have been freely accused of at home. Finally, he surmises that if no search had been made for the ball, and the wound had been dressed aseptically, the unfortunate patient would have been alive now. Valuable as is Prof. Esmarch's opinion on such a point, we regret that this lecture has been published, at any rate so soon. It would not have lost in value by being kept back until the acrimonious discussion on the conduct of the attending surgeons had died out on the other side of the Atlantic. It is proverbially easy to be wise after the event, and it is an ungracious task to criticise adversely the conduct of men who, under very trying circumstances, were suddenly called upon to act in a grave emergency. We are willing to admit that mistakes may have been committed, but it is a case in which the golden rule is eminently applicable: "Let him that is without sin first cast a stone."—*Lancet*, August 19, 1882.

COFFEE AS A DISINFECTANT.—M. BAIBIER (*France Méd.*) finds powdered roasted coffee an excellent deodorizer and disinfectant. The coffee is simply scattered over and about the place or thing requiring disinfection. He has used it in autopsies and on bodies a stinking mass of putrefaction, also as a dressing to foul virulent ulcers.—*Canadian Journal of Medical Science*, September, 1882.

THE REST-CURE IN THE TREATMENT OF NEURASTHENIA.—In opening the discussion on the treatment of hysteria, in the medical section at the recent meeting of the British Medical Association, Dr. Playfair spoke in the highest terms of the value of the methods of treatment of this disease introduced by Dr. S. Weir Mitchell; Dr. Albutt, and other members of the association, confirmed the estimate expressed by Dr. Playfair of this method.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending August 26, 1882, indicate that diarrhœa, remittent fever, influenza, and inflammation of the bowels have considerabty increased, that neuralgia, typhoid fever, and cholera infantum have increased, and that erysipelas has decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending August 26, and since, at 15 places, scarlet fever at 8 places, measles at 8 places, and small-pox at 5 places, as follows: at Westwood, Kalkaska County (3 new cases), August 21; in Walker Township, Kent County, and Orange Township, Ionia County, August 21; at Grand Rapids (1 case, convalescent), August 28; and Sebewa Township, Ionia County (10 cases), August 29.

For the week ending August 26, the Sanitary Inspector reports 2 cases of whooping-cough among the immigrants arriving at Port Huron.

IN proposing the toast, "Prosperity of the British Medical Association," at the dinner in the recent meeting, SIR JAMES PAGET used the following happy expression, "Do not let our disputes be very noisy on the scientific side. Remember always that it is only through clear and undisturbed waters that you can see what lies at the bottom. In storms of controversy, there is nothing to be found but the billow that moves to mischief, and the foam that disappears."

THE VALUE OF ISOLATION IN OBSTETRIC HOSPITALS.—From the statistical report on the deliveries in Lariboisière Hospital, published by DR. SIREDY, we learn that in the first period where no attempt was made at separation of recently confined women suffering from various diseases from those in whom the process was normal, one out of every fifteen died. In the second period isolation of such cases brought the mortality down to one in forty-three. In the third period, in which personal disinfection and means to prevent the transmission of contagion were carried out, the puerperal mortality fell to one in fifty-six, and in simple cases one in eighty-eight. In the second year, when the antiseptic precautions reached a higher degree of perfection, the puerperal mortality was reduced to one in ninety-six, and for simple cases one in one hundred and fifty-three.—*L' Union Méd.*, August 15, 1882.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 28 TO SEPTEMBER 4, 1882.

BARROWS, CHAS. C., *Assistant Surgeon.*—Assigned to duty at Fort Grant, Arizona Territory.—*S. O. 130, Department of Arizona, August 21, 1882.*

SMITH, A. K., *Major and Surgeon.*—Granted leave of absence for one month on surgeon's certificate of disability.—*S. O. 131, Department of Arizona, August 22, 1882.*

SKINNER, J. O., *Captain and Assistant Surgeon.*—To take charge of Medical Director's Office Department of Arizona.—*S. O. 131, Department of Arizona, August 22, 1882.*

EGAN, P. R., *Assistant Surgeon.*—Assigned to duty at Fort Bowie, Arizona Territory.—*S. O. 134, Department of Arizona, August 25, 1882.*

WAKEMAN, W. J., *First Lieutenant and Assistant Surgeon.*—Now at Omaha, Nebraska, to report to the Commanding Officer Fort D. A. Russell, Wyoming, for duty.—*S. O. 88, Department of the Platte, August 25, 1882.*

HUBBARD, V. B., *Major and Surgeon.*—Assigned to duty at Fort Wingate, N. M.—*S. O. 172, Department of Missouri, August 28, 1882.*

BROWN, J. B., *Lieutenant-Colonel and Surgeon.*—Granted leave of absence for six months on surgeon's certificate of disability.—*S. O. 200, A. G. O., August 29, 1882.*

Corrigendum.—In our issue of August 19, page 201, 2d column, 7th line, *for* "This view of the possibility and transmissibilty of the puerperal fever poison," *read* "This view of the portability and transmissibility of the puerperal fever poison."

ORIGINAL LECTURES.

PULMONARY APOPLEXY.

A Clinical Lecture delivered at Rush Medical College, Chicago.

BY E. FLETCHER INGALS, M.D.

(Reported by G. B. NICHOLS.)

GENTLEMEN: P. R., the patient whom I present this morning, is forty-four years of age. He has of late been employed as driver on a street car.

He tells us that six weeks ago he was taken sick after exposure for nearly two days to wet and cold. He had been thoroughly drenched with rain and had worn the same wet clothing the following day and until he retired at two o'clock at night. Two hours after going to bed he was awakened by "terrible pain" in the right side, near the nipple. He was very chilly; felt sick at his stomach, and found his face covered with blood, which came from his lung.

He continued spitting clear blood for about twenty hours, raising in all about a pint; for two days later some blood was expectorated at intervals. Subsequently he was very weak, had night sweats, and for four weeks was unable to lie down. He does not know whether he had fever or not.

Upon inquiry into his previous history, we learn that he had been troubled with cough for four months before this attack, and that for twelve weeks it had been very annoying, though not sufficient to interfere with his work. He cannot recollect having been sick at any time previous during his life excepting once, twenty-two years ago, when he was laid up with rheumatism for fifteen weeks. His parents and grandparents were long-lived, attaining an average age of about eighty years. We learn that for six months previous to this attack the patient has been working about eighteen hours every day. Since this attack he has lost some flesh.

At present we find the skin moist, cool, and of a natural color; the pulse 124 per minute, with a peculiar quick and hard stroke, which becomes harder and more decided by elevating the arm. The frequent interruptions in his conversation are due to dyspnœa, which he tells us has troubled him for nine weeks. He has very little cough and no expectoration. The tongue is clean, excepting a thin yellowish coating at the base. The pharynx is natural. The appetite has been good throughout his sickness; the bowels are regular, and the urine normal as far as appearances go.

Upon inspecting the patient we observe marked pulsation in the carotid and subclavian arteries, with epigastric pulsations. In the præcordial region the impulse of the heart is seen over an area of at least four inches in diameter.

The vocal fremitus is alike on both sides over the upper part of the chest, but it is not felt over the lower part of the right side.

On percussion of the upper part of the chest, both sides are alike. Over the præcordia the area of dulness is larger than usual, indicating considerable dilatation of the heart; but this organ is not displaced. On the right side, in front, the pulmonary resonance extends down to the sixth rib, its normal position.

Posteriorly over the scapula and in the interscapular regions, the resonance is alike on both sides. In the lower part of the infrascapular region, on the left side, we obtain dulness. On the right side, in the infrascapular region, there is complete flatness.

On auscultation over the anterior portion of the chest, at the upper part, I find feeble respiration on the right side and normal respiration on the left. Over the lower portion of the left side, both anteriorly and posteriorly, there are crepitant and subcrepitant râles. Over the lower portion of the right side I find a feeble respiratory murmur, extending down to the sixth rib in front, and following the course of that rib behind; below this I do not hear the respiratory murmur at all; but I get fine crepitant sounds, less numerous than on the left side and nearer to the surface. These are probably friction sounds.

The vocal resonance is normal over the left lung and over the upper part of the right. It is very distinct over the whole lower lobe of the right lung, but it is not uniform, there being spots where it is less intense than over the surrounding tissue. There are no tubular sounds.

In listening over the carotid and subclavian arteries, I hear murmurs on both sides, which result from some cardiac lesion. Over the heart a murmur may be heard at the apex, which grows more and more intense as the stethoscope is carried toward the base, until the articulation of the fifth costal cartilage with the sternum is reached. At this point it is louder than anywhere else. The murmur is very distinct in the second intercostal space on the right side and over the second rib and beneath the clavicle on the left side.

With my finger on the carotid pulse, I find that it occurs synchronously with the diastole of the heart.

This case presents an unusual group of signs. The feeble respiratory murmur over the upper part of the right side indicates that the upper lobe of this lung has in some way been involved, and if we were to examine the upper part of the chest alone, this sign, together with the hæmoptysis, would be taken as conclusive evidence of incipient phthisis; but his hereditary and personal history, together with the signs over other parts of the chest, and the absence of cough, render such a diagnosis untenable.

The flatness over the lower part of the right lung would lead us at once to suspect pleuritic effusion, but the exaggerated vocal resonance and the slight cripitating friction sounds over the same region, together with the fact that the upper line of flatness does not change with changes in the position of the patient's body, are sufficient proof that there is not, at present, a collection of fluid in the pleural sac.

The history of the origin of this attack, and the opinion of the most excellent physician who attended him at that time, ought, perhaps, to satisfy us with the original diagnosis of pneumonia. Yet this does not cover the whole case. No doubt the lung was inflamed at first, but there must have been something more than an ordinary inflammation to account for the profuse hæmoptysis, and the marked signs which we find to-day, after six weeks have elapsed.

The crepitant râles which we hear to-day in the left lung might be taken as a sign of acute inflammation of that organ, but the absence of fever, and the patient's general condition, indicate that an acute pneumonia cannot be present.

We have found in this case certain signs which, considered separately, might be taken as conclusive evidence of phthisis, pleurisy, or pneumonia, but which in

the case before us do not point directly to any of these diseases.

Were we obliged to stop here, in our examination, it would be impossible to satisfactorily account for the condition of this man's lungs, but the cardiac lesions which we have discovered, *i.e.*, enlargement of the organ, with aortic insufficiency, throw a flood of light upon the case.

When we first questioned this patient, he told us that he had never before been sick. We were then at loss to account for the cardiac lesions, but by critical questioning, we at length brought to his recollection a severe attack of rheumatism, which occurred twenty-two years ago. However, he persists in the statement that subsequently to that time he had never been sick, nor experienced any difficulty in respiration until within the last few months.

Two interesting questions are suggested by this statement. 1st. Did the rheumatism cause the cardiac disease? and 2d. In case the heart lesion resulted from the rheumatism, how soon thereafter did it appear, and why did it not sooner produce subjective symptoms?

To the first query, I answer, the rheumatism undoubtedly was the cause of the cardiac lesion, for since that time there has been no sickness or accident which would be at all likely to produce such a result, until very recently, and the changes are now much greater than would be found if the affection were of short duration.

To the second question, I answer, that probably if this patient had been examined twenty-one years ago, an aortic obstructive murmur would have been detected, and doubtless the same might have been found at almost any time thereafter.

I often discover cardiac lesions in patients who have not presented a single subjective symptom, and who apply to me for some trifling affection of the bronchial tubes. In such cases I usually find that the apparent cause has antedated the discovery by several years. Such cases present no subjective symptoms, because nature compensates for the lesions by hypertrophy of the heart. In the case before us, there may have been no regurgitation, until the ventricles became much distended, by reason of his excessive work during the last six months, but of this, we cannot be certain.

We may, however, be sure that the lesion was fully compensated for by the hypertrophy, until his long hours of work and short hours of rest weakened the muscular system, so that the evil effects of a crippled heart were manifested by such symptoms as cough and dyspnœa.

The cardiac lesion enables us to understand the cripitant and subscrepitant râles and slight dulness which are found to-day on the left side, as a result of pulmonary œdema; but there must be some other explanation for the signs found over the right lung.

Recurring to the history, we find that after prolonged exposure, and while suffering from a severe cold, the patient was wakened with severe pain in the side and hæmoptysis. From this, and a physical examination of the chest, I conclude that the congestion and swelling of the lining membrane of the air passages, caused by the cold, so interfered with the passage of blood through the pulmonary circuit, that the weakened heart was unable to perform its function. Consequently its action became sluggish and irregular; as a result, clots were formed in the right side, particles of which became detached, and were carried through the pulmonary arteries, until they finally lodged in and occluded the capillaries, the thin walls of which were thus subjected to the same distending force from behind, as the larger arteries. Rupture naturally resulted, the blood diffused itself through the air-cells and bronchioles of the lobules, causing what is termed hemorrhagic infarction, or circumscribed pulmonary apoplexy. The blood which found its way into the larger bronchial tubes was expectorated.

The hemorrhage and the pain were much greater than common in such cases.

Lesions of this kind usually occur in the upper part of the lower lobe of the lung. The hemorrhage is apt to take place from several points, forming, when the blood coagulates, several distinct nodules, varying in size, but seldom larger than a hen's egg, and most of them much smaller. Because of their small size and deep location, they do not usually occasion complete loss of motion and flatness over the affected portion of the lung; but in rare cases the lung tissue itself is lacerated, and a large amount of blood escapes, thus causing diffused pulmonary apoplexy, which is apt to be attended by considerable hemorrhage and severe pain, as in this case.

The laceration of the lung and pressure of blood upon the pleura caused the acute pain at the time of the accident, and eventuated in pneumonia and pleurisy.

As a result of the pleurisy, the whole lung was compressed for a time, and the patient was unable to breathe in the recumbent position, but finally most of the fluid was absorbed, though too late to allow of free expansion of the upper lobe of the lung, hence the feeble respiration in that locality at present. The combined pressure from blood clots and pleuritic effusion with the inflammation of the pulmonary parenchyma, left the lower lobe of the right lung in a state of almost complete consolidation, which still remains.

The prognosis in pulmonary apoplexy depends upon the cause and extent of the lesion, and the previous condition of the patient. When circumscribed pulmonary apoplexy results from cardiac disease, the nodules are usually small, and as the emboli are simply fibrinous clots, the inflammation which follows is not of a destructive character; therefore many of these cases recover, providing the heart lesion is not extensive and the general health has not been impaired. In diffused pulmonary apoplexy, whether resulting from direct injury or rupture of a large infarction, the prognosis is very grave. In most cases death speedily follows, either from shock or hemorrhage; but should the patient survive these, abscess or gangrene of the lung is likely to carry him off in a few days.

In the case before us, the shock, the hemorrhage, and the danger of gangrene have been safely passed, and, were the heart lesions less severe, we might fairly predict several years of life; but here the aortic regurgitation is marked, the heart is considerably dilated, and pulmonary œdema is already present; besides the function of the right lung is very imperfectly performed. Our prognosis, therefore, cannot be very favorable; nevertheless, the patient's general condition is so good, that I expect great improvement for the present, and possibly fairly comfortable existence for a number of months.

I will give this man ten minims of the tincture of digitalis, four times a day, to strengthen his heart, and if this is not sufficient, I will gradually increase the dose to fifteen or twenty minims, providing it does not cause disturbance of the stomach and his kidneys continue to act well. I will also give him three times a day the twenty-fourth of a grain of sulphate of strychnia as a respiratory and cardiac stimulant, and ten minims of the tincture of the chloride of iron, to improve the character of the blood.

His appetite is good, and the kidneys are acting well, so that apart from the treatment indicated, we will only find it necessary to keep the bowels regular. For this purpose I know of no remedy which acts better when cardiac diseases exist than some of the preparations of

euonymus (wahoo). I have generally employed the fluid extract in doses of half a drachm, but it is said that the eclectic preparation, known as euonymine, acts equally well. The dose of the latter is from half a grain to five grains.

ORIGINAL ARTICLES.

IS TUBERCULOSIS A PARASITIC DISEASE?

THIRD PAPER.

BY GEORGE M. STERNBERG, M.D.,
SURGEON, U. S. A.

IN my second paper I reported my failure to find bacilli responding to Koch's color-test in specimens of sputum furnished me by Prof. Hirschfelder as coming from tuberculous patients. I have since found the bacillus described by the method of Ehrlich in the sputum of several phthisical patients.

This method seems to possess decided advantages over that first recommended by Koch, and we learn from the journals that he has himself adopted it.

Whether failure in the first instance was due to the absence of these bacilli from the material examined or to the difficulty of demonstrating them by Koch's method, it is, of course, impossible to say. But as my experiments upon animals inoculated with this material have also been attended with a negative result, it seems fair to assume, as suggested when the examination was made, that the material was not of the right kind.

In the *British Medical Journal* (July 1, 1882, p. 7), I find the following statement in a lecture on the Antiseptic Treatment of Pulmonary Consumption by Burney Yeo, M.D., F.R.C.P. "I have lately had careful search made by very competent workers with the microscope, in the expectoration of patients with advanced phthisis, as well as in sections of typical tuberculous mesenteric glands; but they have not yet succeeded in finding the organisms described by Koch."

It hardly seems probable that these negative results are entirely due to inexperience in the application of Koch's method, as his directions are very explicit and there is no difficulty in following them with precision. But, if all cases of consumption of the lung were tuberculous, which is probably not true, it does not follow that the sputa of phthisical patients comes at all times from the tuberculous portion of the lungs; for these patients as well as others are subject to pneumonia or to bronchial catarrh.

In my first experiments upon rabbits the material was introduced into the subcutaneous connective tissue through a narrow opening in the skin, made with a sharp instrument. The inoculation was made at the side of the neck, and from two to five minims of the viscid sputum was introduced by means of a grooved director or a silver probe.

Experiment No. 1, May 26, 1882.—Three half-grown rabbits were inoculated as above described with the sputa of three patients in the City Hospital, procured for me by Prof. Hirschfelder for these experiments and believed to be from tuberculous patients. On June 2d, one of these rabbits received a second inoculation with tuberculous material from a portion of lung obtained the same day at a post-mortem examination made at the City Hospital. This material was carefully examined by Koch's method with a negative result so far as the presence of the bacillus described by him is concerned.

No noticeable result followed these inoculations, with the exception of the formation of a circumscribed abscess, of small size, at the point of insertion, in one of them. The animals continued to eat well and to grow in size, without losing flesh. On the 2d of July these rabbits were killed and carefully examined. The lungs and other organs appeared perfectly normal, and no evidence of tubercular deposit was found in these, or in the serous membranes.

Experiment No. 2, May 30.—A large full-grown rabbit was inoculated as before, with sputum obtained the same day from Prof. Hirschfelder, and believed to be from a tuberculous patient. An abscess formed at the point of insertion, which was opened June 17th, and the cheesy contents examined by Koch's method, with a negative result, as regards the presence of *Bacillus tuberculosis*.

This animal was killed July 15th, and carefully examined, but no evidence of tubercular deposit in the lungs or elsewhere could be discovered.

July 29. — A fresh specimen of sputum was obtained from Prof. Hirschfelder this day, and carefully examined both by Koch's and by Baumgarten's method. A few bacilli were seen by Baumgarten's method, which possibly respond to the test—failure to stain by methyl violet, after treatment with solution of potash—but the result is not considered satisfactory, as the bacilli referred to appear to have less color than others in the same preparation, because of their smaller diameter, rather than to be entirely without color. The possibility of mistaking the contour of the nuclei of pus-cells for bacilli is more than ever apparent.

August 8. — Received from Prof. Hirschfelder a supply of aniline oil, and a fresh specimen of sputum from a case pronounced undoubtedly tubercular consumption.

By the method of Ehrlich, the presence in this specimen of bacilli, which retain their color when treated with nitric acid after being stained with fuchsin, was clearly demonstrated. This color-test is very definite, and distinguishes clearly these bacilli from other micro-organisms—bacilli and micrococci—also present in the same preparation. The latter are entirely colorless, while the former are deeply stained by the fuchsin. As stated by Koch, this color is still more apparent, when the condensing lens is moved forward, so as to strongly illuminate the field. *Pseudo-bacilli* may also be seen, which, by careful focusing, are resolved into the line of junction of two cells in juxtaposition, or the margins of cell-nuclei.

Having found in the sputum of a tuberculous patient the bacilli described by Koch, the next step seemed to be to ascertain whether, by the same method, similar bacilli might not be demonstrated in non-tuberculous sputa. My own saliva or a small mass of muco-pus coughed up from my lungs—I have a slight bronchial catarrh—did not contain bacilli responding to the color-test.

August 10.—At my request, Prof. Hirschfelder procured for me eight samples of sputum, some from tubercular and some from non-tubercular patients, the diagnosis not being communicated to me, as I desired to ascertain whether my report with reference to the presence of Koch's bacillus would correspond with his diagnosis of the cases. The bacillus was found in three specimens, and Dr. Hirschfelder subsequently informed me that these came from phthisical patients, but that three other specimens, from which I obtained a negative result, were also from cases of the same character, while two were from non-tubercular patients. Having received all of these specimens at once, I only found time to mount one slide of each, while the material was fresh, and consequently do not consider my negative result in the three cases pronounced tubercular as evidence of the absence of the bacillus from these specimens. It is evident, for reasons already given, that repeated examinations would be required to definitely establish the absence of the bacillus, although its presence may be demonstrated by a single preparation.

12th.—Received a specimen of sputum from a case in the post hospital at Angel Island, Cal., diagnosed by Surgeon Brooke, U. S. A., as pulmonary consumption. Four slides were prepared, Ehrlich's method, and the bacillus of Koch was found in all in greater abundance than in specimens previously examined.

14th.—Recieved a specimen of sputum from a patient of my own, a married woman living in the suburbs of San Francisco, whose case was diagnosed by me as consumption several months since. There is evidence of tubercular deposit at the apex of left lung, several hemorrhages have occurred, and a distressing cough in the morning results in the expectoration of a solid, greenish-yellow mass. At my request, this morning expectoration was received in a clean, wide-mouthed bottle, and sent to me at once. Microscopical examination of preparations, stained by Ehrlich's method, demonstrated the presence of Koch's bacilli.

Note.—The following animals have been inoculated with sputum from this and the preceding (Dr. Brooke's) case, viz., four rabbits, one guinea-pig, and a pup six weeks old. The results of these inoculations will be reported in a future communication.

As to the abundance of these bacilli in the specimens of sputum examined, I may say that they are not very abundant. While common forms which are decolorized by the action of nitric acid, are often found in considerable numbers, these deeply-stained bacilli are usually solitary, or, at most, but four or five are seen in a single field. They appear either within, or external to, the pus-cells. It is probable that in the former case they are sometimes only covered by the cells, which are flattened out by the drying and heating process to which the preparation is subjected. Indeed it would be difficult, from a mere inspection, to decide with certainty whether this is the case, or whether they are actually within the cells. The fact that several are sometimes found within a single cell, while those without are commonly solitary, indicates, however, that they are sometimes at least enclosed within the cells, and, therefore, in all probability, developed in this situation. They are most easily seen in fields where the material is spread out very thin, and in which the pus-cells do not overlie each other and have been thoroughly decolorized by the nitric acid bath.

MORPHOLOGY.

Koch describes the bacilli of tuberculosis as follows:

"They are very thin, and from one-fourth to one-half as long as the diameter of a red blood-corpuscle. They may also be longer, sometimes they even reach the length of the full diameter of a blood-corpuscle." (*Berliner klinische Wochenschrift*, No. 15, p. 222, 1882.)

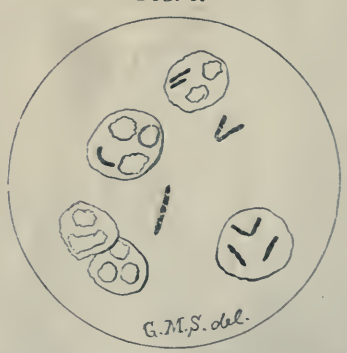
"The tubercle bacilli are at least five times as long as thick, and often much longer in proportion to their thickness" (*l. c.*, p. 223).

"The bacilli may also be examined without staining. In this case it is necessary to have a specimen containing a considerable number; for example, from a gray tubercular nodule from the lung of an inoculated guinea-pig. A little of this material may be mixed with distilled water or blood-serum. . . . The bacilli appear then as very small rods which show only molecular movement, but not the slightest spontaneous movement. Under certain circumstances the bacilli, later, show spores, in the animal body, and, indeed, most of the bacilli have two to four oval spores, which are arranged at equal distances along their length" (*l. c.*, p. 222).

This description answers perfectly for the bacilli seen by me, but scarcely serves to distinguish these from others, which are commonly found in localities which preclude the idea that they are pathogenic, at least not under ordinary circumstances. (See Figs. 2 and 4.)

With my Zeiss' $\frac{1}{18}$ nom. ol. im. objective, I have been able to distinguish the oval spores described by Koch in a few of the rods seen in my preparation. Not infrequently in the longer rods a slight constriction is seen at the middle, and in some cases the rod is bent at an acute angle at this point, as seen in my drawing, Fig. 1. This is no doubt the result of spontaneous fusion, and indicates that this bacillus, like other micro-organisms of its class, multiplies by division as well as by the formation of endogenous spores.

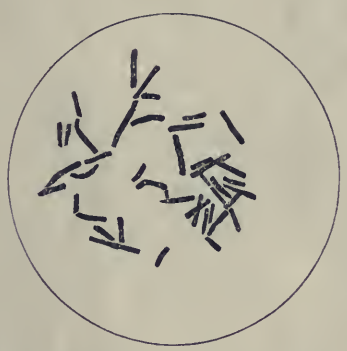
FIG. 1.



The rods are sometimes crescentic in shape, as shown in the pus-corpuscle containing a single one, Fig. 1. My attempts to photograph this bacillus have not been very successful, for the reason that the fuchsin-staining, although very decided optically, is apparently almost transparent for the actinic rays. I have had great difficulty in projecting an image which could be seen and focused on the screen. Moreover, in consequence of the small number to be found in a single field, this mode of illustration would not be satisfactory. I have, however, made several negatives, showing a single bacillus well enough to enable me to measure it and compare it with bacilli from other sources. This comparison shows that they do not present any morphological characters by which they can be distinguished with certainty. The bacilli shown in Fig. 3 resemble them very closely indeed, and, for aught I know, may be identical with them; for when this photograph was made, the color-test was not known.

The circumstances under which the bacilli represented in this figure were found have always made them possess a special interest for me, but, unfortunately, I was only able to verify their presence in

FIG. 2.



the unusual locality in which they were found, and to make photographs of them, as other pressing obligations prevented me from attempting to cultivate them and to experiment with reference to their possible pathogenic properties. They were found in the pericardial sac and in the substance of the heart of a rabbit which died as the result of a subcutaneous injection of contaminated water (No. 5), sent to the biological laboratory of Johns Hopkins University, by Prof. Mallet, of the University of Virginia, for this purpose, in connection with his experimental research (for the National Board of Health) upon drinking-water. I do not know to this day the source of this particular sample of water, but the results following its injection beneath the skin of a rabbit were very pronounced and differed from any previously obtained by me in similar experiments. The animal died within a few days after the injection, and upon post-mortem examination the pericardium was found to be inflamed and covered with fibrinous exudation, while in the substance of the heart there were numerous white-colored collections of a semi-solid material, which, upon microscopic examination, proved to contain the bacilli here figured. The serum contained in the pericardial sac also contained these bacilli in abundance.

FIG. 3.

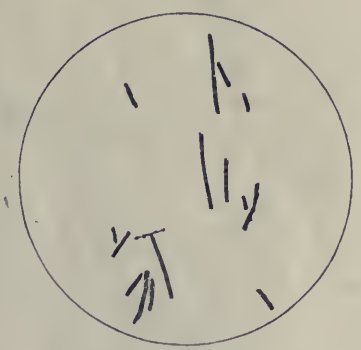


Figure 2 shows bacilli also photographed in Baltimore from normal human saliva.

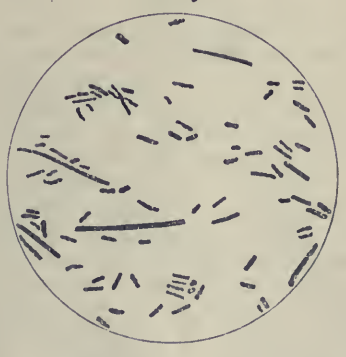
In Figure 4 we have bacilli and other bacterial forms, developed in Koch's staining fluid as stated in my previons paper (THE MEDICAL NEWS, July 22, p. 87). The amplification in this figure is but 500

FIG. 4.

diameters, while in Figures 1, 2, 3, and 5, it is 1000 diameters.

In Figure 5 we have again bacilli, which were

FIG. 5.



found upon a glass slip exposed over swamp-mud (artificial marsh) in my laboratory in New Orleans —summer of 1880. (*Vide* Special Report to Na-

tional Board of Health. *Supplement No. 14 to Nat. Board of Health Bulletin.*)

Figure 6 is from a photo-micrograph of *Bacillus anthracis* made in Baltimore last summer from material obtained by inoculation and culture experiments, from stock which had been in the possession

FIG. 6.

of Dr. Burden-Sanderson for seven years, and was sent by him to Prof. Martin of Johns Hopkins University. (*Vide Philadelphia Medical Times*, June 18, 1881, p. 593.) In this figure rods and isolated spores may be seen, also a long filament containing numerous spores arranged at regular intervals.

It is difficult to represent these micro-organisms by means of wood-cuts exactly as they appear in the photo-micrographs; but these cuts will at least be free from misrepresentation, due to the personal equation of the original observer, as the cuts are all made by the wood engraver, under the direction of the editor of this journal, from photo-micrographs made by myself, with the exception of Fig. 1, which, as already stated, I have drawn from the microscope, with an indifferent photo-micrograph to guide me as to dimensions. In this figure I have also endeavored to show the *pseudo-bacilli*, which I have thought it necessary to point out for the benefit of inexperienced persons who may be inclined to resort to the microscope for the diagnosis of their tubercular cases. The point of contact between the two pus cells in the lower part of the figure and the right hand margin of a nucleus in the cell containing three nuclei, are intended to exhibit this appearance.

Perhaps it will be thought by some, that a proper recognition of the merits of Koch as an accurate observer, of the fact that the Emperor of Germany has already rewarded him for his discovery, and my own statement, that I find the bacilli described by him in the sputa of tuberculous patients, are sufficient reasons for removing the interrogation point from the title of this paper. But the atmosphere of this remote locality is more favorable for interrogation points than is that—Berlin—in which the correspondent of THE MEDICAL NEWS, J. T. W., writes his interesting letters; I must therefore continue to fly my colors at the risk of being considered obstinately conservative and exacting. Dr. Koch, himself, admits that the demonstration is only made complete by his inoculation and culture experiments, and the results obtained by these, I am not yet able to confirm. This serial must, therefore, be still further extended.

SOME OF THE NERVOUS AFFECTIONS WHICH ARE LIABLE TO FOLLOW NEGLECTED CONGENITAL PHIMOSIS IN CHILDREN.

BY NORMAN H. CHAPMAN, M.D., B.S.,
PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE UNIVERSITY OF KANSAS CITY.

THE condition of congenital phimosis is a simple one. The foreskin is long and abundant, while the mucous membrane lining it is short and undeveloped. The defect or narrowing of the preputial orifice rests almost entirely in the contracted mucous membrane, rather than in the lax and overlying integument.

A penis congenitally deformed by phimosis is usually somewhat dwarfed or atrophied. The trouble is always a source of inconvenience, interfering with cleanliness as well as comfort, and it not unfrequently becomes the source of marked disease. Thus in children irritating secretions from the sebaceous follicles—the "smegma preputii"—are retained under the elongated and tight foreskin, and produce a considerable amount of local irritation, which is usually sufficient to keep the organ almost constantly in a state of undue excitement. Again, when the preputial orifice is smaller than the urethral meatus, and there is difficulty in micturition from the backing up or retention of urine about the glans, the irritability of the bladder which is invariably associated with it, not infrequently produces symptoms resembling those of calculus. Many a case of suspected urinary calculus in a young child, has after physical examination turned out to be aggravated congenital phimosis. Then, too, calcareous concretions sometimes form between the prepuce and glans. In my first operation for phimosis, upon a colored child aged five years, I found four well-formed calculi, of millet-seed size, embedded in a mass of gritty smegma. In India these concretions are very common, frequently forming in enormous quantities. Whishaw tells us that from a single native of India he has removed no fewer than 426 of these small calculi.

It is my principal desire at this time, however, to call attention to some of the varied nervous troubles which are liable to be brought about by neglected congenital phimosis, and I shall endeavor to illustrate the types of the maladies produced by short histories of appropriate cases taken from hospital records and my own private note-book.

There is scarcely a case of moderately severe congenital phimosis which does not in some way show its characteristic undermining influence upon the constitution and general health of the sufferer. In a fair proportion of the children thus affected, perhaps the only evidence of failing nutrition noticeable will be in the changes in disposition and in the setting up of an indistinct train of nervous phenomena. In children previously brisk and cheerful, there is a striking change of temper, they are now peevish, fretful, and discontented. The mental energies fail; the child is inattentive and forgetful at school; and there are disturbances of

appetite and of sleep. But in a certain proportion of these cases the evidence exhibited will be of a more serious character. The nervous system will be undermined to such an extent as to result either in chorea, or in some of the varied forms of reflex or peripheral palsy; and it is this class which I wish more especially to illustrate by a series of cases.

The tendency towards the development of choreic attacks is fairly shown in the following case:

P. F., a delicate lad, aged 7 years, applied to the out wards of the Philadelphia Orthopædic Hospital for suspected spinal trouble. Upon examination, although the spine was found to be perfectly normal, the child suffered much from irritability of the bladder; during the day he would pass small quantities of water frequently, and was continually wetting the bed at night and crying out with pain. The mother states that he is a cross, irritable child, cries a great deal, and complains of suffering pain on passing water, that he has been at school, but was sent home on account of inattention and forgetfulness, and that he was frequently punished by the schoolmaster for bad temper. Together with these symptoms of irritability of the bladder, the child exhibited certain awkward and incoördinate muscular movements of the body and upper extremities. These motor disturbances were not under the control of the will, but markedly exhibited their disobedience when a volitional act was attempted. When the child would attempt to pick up a small object, for instance, or do any similar act in obedience to the mandates of the will, it was done with that lack of coördination peculiar to the more common form of chorea. These incoördinate movements were not the monotonous jerking muscular contractions of the epileptic or hysterical case, but were marked by a good degree of variety, and so combined as to give to the observer the aspect of design in their execution. The muscles of the face also executed at regular intervals a peculiar grimace, and the shoulders were from time to time alternately raised and sunken. There was a faint anæmic heart murmur, but no organic lesion. The condition of the penis was that of phimosis. The prepuce was long, and the mucous lining membrane largely adherent to the glans. The margins of the prepuce were swollen and inflamed. The lips of the meatus, which could with difficulty be seen, appeared red and pouting.

Circumcision was performed. The child placed upon a tonic and nutritious dietetic regimen, with the occasional employment of the cold douche to the spine, and in two weeks after the parts had entirely healed, the irregular choreal manifestations had disappeared, but the lad still had the reputation of a bad temper.

This is not an isolated case. I have seen several whose histories were essentially the same, and its citation only adds another exciting cause to the group of choreal neuroses.

Paralysis of a purely reflex nature not unfrequently follows aggravated congenital phimosis. This fact was pointed out some years ago by Sayre, and has since that time been repeatedly observed. The types of reflex palsy, most common from this exciting cause, are of the nature of paresis rather than of total palsy, although there have been cases where the loss of power was complete. The parts most usually affected are the lower extremities, either singly or together; the arms, either the right or the left separately; and at times special muscles or groups of muscles. The following case will illustrate this form of reflex palsy as it occurs in the lower extremities:

A. L., æt. 5 years, a colored child of strumous parentage, was brought to me suffering from partial loss of power in the lower extremities. The mother's history of the onset of this trouble was very imperfect, but from her I learned that about four months previously the child had in rapid succession several spasms or convulsions, in which consciousness was apparently lost, and that after these attacks there was noticed some loss of power in the lower extremities. At first, not much attention was paid to this condition, but the child grew gradually worse, and as I first saw him the loss of power was well marked. The child could not stand alone; he had little or no use of the leg muscles, and only a limited amount of control over those of the thigh. There was an absence of reflex and automatic muscular movements upon irritation of the peripheral nerves of the part. Sensation, as tested with the æsthesiometer, remained nearly normal. There had never been manifestations of any derangement in the cerebral function. The electro-muscular contractility, as tested by the induced current, was very feeble, but there appeared to be little or no atrophy of the parts. The child appeared fairly well nourished, but as the mother expressed it, was "excessively nervous," "never still," and occasionally wet the bed at night. The child had phimosis, and the tissues about the preputial orifice were considerably inflamed, and, what is not very common, dotted with numerous small ulcers.

Feeling confident that the loss of power in this child's case was mainly of a reflex character, and dependent upon genital irritation, I began his treatment by circumcision, and followed it up by employing local massage, galvanism, and afterwards faradization, with mild tonics, and a short course of the iodides. The case made a rapid and almost complete recovery. In a month's time the child was able to walk about without much difficulty. After this I did not see the case.

Reflex palsies dependent upon neglected congenital phimosis, are not always of so severe and extended a nature as seen in the case just mentioned. The loss of power may be confined to a single member, or to a single muscle or set of muscles.

About a year ago, I saw in consultation a child, from Maryland, who was suffering from local palsy of the right upper extremity. The loss of power in the muscles of the forearm and hand was almost complete, but was not at all marked in the muscles of the arm and shoulder. Reflex and automatic movements were not easily excited, sensation was impaired in the hand affected, and there were evidences of beginning vaso-motor and trophic disturbances. The child had aggravated congenital

phimosis. In consultation I expressed the belief that the palsy was of a reflex character, and dependent upon the peripheral irritation set up by the neglected congenital deformity. This view was not entertained by the physician in attendance, but nevertheless, circumcision was performed, and in due course of time the child regained the use of the palsied member.

Single muscles are occasionally affected. Witness the following case of convergent strabismus from paralysis:

Willie W., æt. 6 years, a fairly well-nourished child, of healthy parents, applied to the surgical wards of the Orthopædic Hospital in reference to a bodily deformity. Beside the orthopædic trouble, it was noticed that the child had convergent strabismus. The mother stated that the eye trouble was of slow growth; that at first it was only noticed when the child was attempting to look at some particular object—that is, the condition at that time was what is known as periodical squint—but that of late the crossing had become constant and the eye somewhat fixed in its unnatural position.

The child suffered from the usual symptoms of irritability of the bladder; had marked phimosis, the penis was unduly large, appeared to be in a state of chronic excitement, and during a slight examination became erect. Circumcision was performed, the case carefully watched, and shortly after the parts had entirely healed we saw no more of his strabismus.

In cases of paralytic or spasmodic strabismus there is a condition of deficient innervation of one or more of the muscles of the ball of the eye. The condition is more or less the result of a vitiated nerve and blood supply, and has the effect of gradually lessening the power of the affected muscle until the eye is rendered more or less fixed in position. Cases of strabismus which are of this nature are easily distinguishable from those of concomitant squint, by observing the movements of the affected eye while vision is temporarily occluded from its unaffected fellow. For instance, if in a case similar to the one just mentioned, the sound eye be covered, the one affected cannot be readily directed towards any desired object, its mobility is impaired; whereas in the ordinary cases of concomitant squint the muscular innervation is normal, the affection of the muscle being practically only one of shortening, as is demonstrated by the perfect mobility of the ball of the affected eye when its fellow of the opposite side is closed. The impaired mobility *or fixation* of the eye-ball does not of itself indicate that the existing strabismus in this case was from palsy of peripheral origin; but when we consider in connection with this fact, the gradual onset of the trouble—how it was at first only periodic squint and afterwards became constant—the unimpaired mental faculties and the non-existence of other morbid phenomena indicative of brain or cord trouble, and its ready disappearance after the removal of the source of peripheral irritation, we can scarcely consider it anything else but one of those rare forms of purely reflex palsy in which only a single muscle is affected.

As to the manner in which the irritation of the peripheral nerves of the genitalia consequent upon congenital phimosis, produces such reflex palsies, it is not my present purpose to speak. I will only say that, in the opinion of Brown-Séquard,[1] "they result from chronic irritation of the genito-urinary organs, with secondary contraction of the vessels, of the cord, and atrophy of the corresponding parts." Romberg and Stanley consider them to be "motor-spinal palsies due to the suspension of the sensory influence of the fibres of the sympathetic system." According to Gull, the palsies in question result from the propagation of the inflammation in the urinary passages to the spinal cord. And Levisson has pretty clearly demonstrated that these palsies were "due to an arrest of the functions of the motor nerve-centres in consequence of excessive irritation of the sensory fibres at the periphery."

Before dismissing this brief mention of some of the maladies which occasionally follow neglected congenital phimosis, I should like to call attention to two cases which are not of a nervous character, but which will not be without interest. They are as follows:

C. and W., two little Italian boys, brothers, aged respectively 3 and 4 years. They were brought to the hospital for right-sided scrotal hernia, developed in each since their birth. Upon examining the herniæ, as to shape, size, and color, their appearances were remarkably similar. If there was any difference, it was in size; that of the elder boy being, perhaps, a trifle the larger hernia. They were each fully up to a pullet's egg in size. The penis of the oldest child was abnormally large, and appeared as if it were habitually in a state of semi-erection. The father remarked that he had noticed this child to rub and pull at the organ as if in pain, the titillation being no doubt a large factor in the almost constant excitement of the organ. There was marked phimosis. The preputial orifice was very small, only permitting a knitting-needle-like stream to flow during micturition, so that the urine collected between the prepuce and glans in a pouch-like manner. The margins of the contracted prepuce were red and angry, and there were noticed lumps of hardened smegma back of the corona. The condition of the younger child was much the same as that of the one just mentioned, except that the penis was very small, atrophied; there were no collections of smegma preputii, and the prepuce was largely adherent to the glans. These children were both peevish, fretful, cried a great deal, and strained heavily with every attempt to relieve an irritable bladder.

Circumcision was peformed in each of these cases; the herniæ reduced and held in place by a properly fitting truss. The mother remarked several weeks after the operations were performed that the change wrought in the disposition of the boys "was something truly remarkable."

Dr. Louis A. Sayre[2] has recently recorded two cases very similar to the above occurring in his private practice, in a pair of male twins. In Dr.

[1] Putzel's Translation of Rosenthal on "Nervous Diseases," vol. ii. p. 152 *et seq.*

[2] Medical News and Abstract, June, 1880, p. 326.

Sayre's cases the herniæ were inguinal, and were believed to be caused by excessive crying, and by straining efforts during micturition. There was severe phimosis in each of the twins, and circumcision was performed, but we are not told as to the result.

From the above citation of cases it will be seen that the long and contracted foreskin with which so many young children are born is not always a harmless deformity. Indeed it may be truly said to be the cause of a great variety of secondary complications, which are oftentimes more serious than the original trouble. We have no knowledge of the exact relation which the cases of congenital phimosis bear to the number of male births. I think if we had, the proportion would be much larger than is ordinarily anticipated. I conceive that it is always good surgery to correct this deformity, wherever it is at all aggravated, as a precautionary measure, even though no symptoms have as yet presented themselves to indicate the early development of such troubles as I have here endeavored to illustrate. Moses was a good sanitarian, and if circumcision was more generally practised at the present day, I believe that we would hear far less of the pollutions and indiscretions of youth; and that our daily papers would not be so profusely flooded with all kinds of sure cures for loss of manhood.

A CASE OF EXTERNAL PERINEAL URETHROTOMY,

UPON A CONDUCTOR, FOR A RESILIENT STRICTURE OF THE DEEP URETHRA, AND THE MEDIAN LITHOTOMY OPERATION FOR THE REMOVAL OF A FOREIGN BODY FROM THE BLADDER AT ONE SITTING.

BY HENRY I. RAYMOND, M.D.,
ASSISTANT SURGEON U. S. ARMY, LATE HOUSE SURGEON TO BELLEVUE HOSPITAL.

WHILE halting as between an internal urethrotomy and an external perineo-urethral section for a deep resilient stricture of the urethra, the choice or manner of operation was decided in my mind by the lodgement in the bladder of four inches of a hard rubber catheter by meddlesome interference and the failure to extract the same with the urethral forceps, and inability to obtain a lithotrite for a final trial by extraction. The indications seemed to be to make a perineal section, incise the urethra at the seat of stricture, and extract the foreign body through the perineal wound.

I. D., Irish, in fair physical condition, but obdurate and obstinate, had had six gonorrhœas, the first attack being fourteen years ago. Seven years subsequently an embryonic stricture appeared, and in course of time encroached upon the calibre of the urethral canal so as to necessitate instrumental dilatation.

On seeing the case for the first time three months ago, I found a stricture at five and a half inches, which grasped tightly a No. 6 conical steel sound, but would dilate readily, by virtue of its resiliency, up to a No 10. After practising gradual dilatation not oftener than twice a week for two months, a No. 15 steel sound passed snugly. Since then the same calibre has been reached at each sitting, but it has been necessary to begin the dilatation with much smaller numbers. Ten days after the passage of a No. 15 steel sound, the patient came to me at six o'clock in the evening with a retention of urine of a few hours' duration, which was relieved by a large-sized catheter, introduced after the passage of Nos. 7, 8, and 9 steel sounds.

It not being advisable to treat the patient, a military convict, out of quarters, I tied in his urethra a well-oiled, but too brittle, vulcanized rubber catheter, and instructed him in three hours to void his urine, and then slowly to withdraw the catheter for the night.

Immediately after I left him, he tells me, he untied the catheter, shoved it backwards and drew it forwards repeatedly in his urethra, to see how tightly it might be grasped, and finally withdrew the major portion of the instrument, leaving four inches of hard rubber tubing in his bladder. Patient's obstinacy prevented the removal of the foreign body until the lapse of thirty-six hours, when symptoms of vesical irritation—pain and frequent micturition—began to manifest themselves. Thereupon patient was etherized, and being placed in the lithotomy position, the bladder was sounded, and the fragment of a catheter detected.

Assistant Surgeon E. C. Carter, U. S. A., then passed a lithotomy staff, and, holding the staff at a perpendicular to the hypogastrium, exactly in the middle line, pressed lightly against the flesh of the pubic cushion, the scrotum being elevated.

Having secured an exact symmetrical position of patient's hips and buttocks, the operator, with the left forefinger in the patient's rectum, steadied the staff and guided a long narrow-bladed bistoury, entered at a point half an inch above the anus, into the groove of the staff at the apex of the prostate. The knife, with its cutting edge uppermost, incised the urethra a few lines in length, and was then withdrawn upwards, making an incision in the perineum of an inch and a quarter. The procedure thus far formed the initial step in common to both subsequent operations, namely, the urethrotomy with relief of the stricture, and the "lithotomy" with extraction of the imprisoned catheter.

In the next step the longitudinal cut in the urethra was extended for almost two inches, liberating the stricture and affording ingress into the bladder. The operator's left index finger was then removed from the rectum, and, being well coated with vaseline, was entered at the perineal wound, and by a gentle twisting and boring movement effected the dilatation of the prostate and an entrance into the bladder, the finger being guided surely into that viscus by following along between the upper urethral wall and the *concavity* of the staff.

When this simple rule has not been conformed to, it has happened that the dilating finger has made for itself in the abundant cellular tissue a cul-de-sac, in which, of course, the presence of a vesical calculus failed to be demonstrated. Dr. Carter now withdrew the lithotomy staff from the urethra. The finger once in the bladder, its bas fond was

explored to the left and then to the right, and the foreign body, felt in the latter situation, was extracted by the urethral forceps aided by the left forefinger of the operator.

Patient was then put to bed on his back, with his lower limbs approximated, and the scrotum was elevated by a suspensory bandage as a preventive measure against urinary infiltration.

The loss of blood amounted to not more than a tablespoonful, although there existed external hemorrhoids from constant straining at micturition. The shock to the patient was very slight, but to prevent urethral chill, quinia sulph. grs. x and morphia sulph. gr. ¼ were given as patient came from under the anæsthetic. The perineal wound was left free and open, inasmuch as Menzel, and, later, Keyes, have shown, by traumatic infiltration in dogs, and by hypodermic injection of healthy urine in man, that normal urine is innocuous to cellular tissue and membranes denuded of their epithelium. No catheter was retained or passed, since its presence has often been the cause of urethral chill, ulceration and incrustation, and prevention of union by the first intention. The urethral wound was cleansed twice daily with a 2½ per cent. carbolic acid solution, and balsam of Peru and marine lint applied.

The temperature has not risen at any time above 99.8° Fahr. Subsequent to operation patient received tinct. ferri chlor. gtts. xv, well diluted, and quinia sulph. grs. iij, t. i. d., and his urine was rendered bland and unirritating by potash and diluent drinks.

I passed a full-sized, well-polished steel sound on the second day and on each third day thereafter.

One week from date of operation the urine began to pass in some measure by the natural channel out through the meatus urinarius, and the ratio to the whole quantity gained an increment at each subsequent act of urination up to within the third week, when the urethral rent had closed and the whole stream of urine was ejected from the distal orifice. At no time did patient lose control of his vesical sphincter. No untoward symptom presented itself, and patient was permitted to leave his bed on the eighth day. The wound healed without discharging one drop of pus.

Catheterization can now be made with a full-sized instrument, and the stricture may be said to be "cured," with the proviso that a large, highly polished steel sound be passed every week or fortnight as long as for him the law shall hold good that irritation of living organic fibrous tissue will cause retraction.

HOSPITAL NOTES.

UNIVERSITY HOSPITAL.

(Service of PROFS. D. HAYES AGNEW AND JOHN ASHHURST, JR.)

FOUR CASES OF ABDOMINAL INJURY.

(Reported by THOMAS D. DUNN, M.D., RESIDENT SURGEON.)

CASE I.—J. R., æt. 15, admitted under care of Dr. Agnew, March 20, 1882. While lifting a box into a wagon, the box slipped, striking his abdomen. The patient fainted, and lay unconscious for several minutes, and when brought to the hospital his condition was alarming—a rupture of some abdominal viscus being suspected. The symptoms were those of profound shock. He lay listless and helpless. There was great pallor, and the skin was covered with a cold sweat; the temperature in the axilla was only 97° F.; the heart's action was slow and slightly intermittent; pulse small and compressible. Abdominal tenderness was not marked and no evidence of external injury could be detected. There was no vomiting or retention of urine. The treatment consisted in the application of external heat, and in the administration of carbonate of ammonium and a moderate amount of stimulus. For the epigastric tenderness a large poultice was applied to the abdomen. In a few hours he reacted, but the belly continued tender to the touch, and there was considerable prostration for forty-eight hours. He was discharged three days afterwards, cured.

CASE II.—C. R., æt. 17, brakeman W. C. & P. R. R., admitted into house under care of Dr. Ashhurst. In walking from one box car to another he fell between them —striking with his abdomen on the circular wheel of an ordinary brake. His condition on admission was similar to that of the previous patient—one of severe shock. The abdominal tenderness was more marked, and there was slight contusion of the walls of the abdomen. The temperature was subnormal and catheterization was required to empty the bladder. The shock was treated in the same way as in the preceding case, and after reaction was thoroughly established calomel and opium were prescribed. There was some vomiting, but no tympanites or constipation. He left the hospital well in one week after admission.

CASE III.—P. N., æt. 43, seaman, admitted December 5, 1881, under care of Dr. Ashhurst. The injury was sustained by falling down the hatchway of a vessel and striking with abdomen on a beam. The patient was picked up unconscious, and when brought to the hospital complained of pain in the abdomen, which was tender to the touch and considerably tumefied. There was great anxiety of countenance; the pulse slow and feeble; skin cold and clammy; temperature subnormal; respiration shallow and gasping. Diffusible stimulants, external heat, hot poultices to abdomen, and the free administration of opium constituted the treatment. The urine had to be drawn off, but it contained no blood. On the 6th his condition became more alarming. The belly was enormously distended with gas and very painful to touch. The dyspnœa was more marked, and there was frequent vomiting. Temperature was $100\frac{3}{5}°$; pulse 60. Dr. Ashhurst directed an increase of opium, mercurial inunctions over abdomen twice daily, to be followed by hot poultices, and in case the dyspnœa threatened the life of the patient, a resort to aspiration. On the 7th the pulse dropped to 48, but the temperature remained about 100°. The violent vomiting rendered rectal alimentation necessary. On the 7th day after admission his gums became sore and the mercury was stopped, and the day following there was a copious movement of the bowels, the first since admission. It was followed by decrease in dyspnœa, vomiting, and tympanites. The patient's temperature ranged from 99° to 101°, and pulse from 48 to 64 for ten days. He left the house convalescing twenty-eight days after admission.

CASE IV.—B. S., æt. 24, laborer, admitted March 13, 1882, under Dr. Agnew's care. The injury was received by the kick of a horse, to the left of the median line and below the floating ribs. There was considerable shock on admission, from which the patient slowly reacted. He passed a large quantity of blood from the bladder soon after receiving the blow. The same

evening the belly began to swell with abdominal pains and tenderness, and the vomiting of everything taken into the stomach. On the 14th, the blood had almost disappeared from the urine, but catheterization was still required; the distention of abdomen increased with increase of tenderness and constant vomiting of bile; temperature 100°, pulse 72 and very feeble. Mercurial inunctions, with hot poultices and the free administration of opium, as in the previous case, constituted the treatment. In addition to this, nearly every remedy known to allay the irritability of the stomach was unsuccessfully tried. Food was given by rectum. Catheters were frequently passed into the rectum and turpentine injections employed, hoping to effect an escape of gas, but with very imperfect results. The dyspnœa and vomiting on the 17th became more urgent, and early on the morning of the 18th an attempt was made to remove the gas by the insertion of a large stomach tube far into the rectum, and failing in this, a small trocar and canula was inserted in the median line about two and a half inches below the umbilicus. A large quantity of gas escaped and immediate relief of both vomiting and dyspnœa followed. The patient expressed himself relieved, and went to sleep and not waking until daylight, when there was a large movement of the bowels. He rapidly improved, and in a few days was convalescent.

Remarks by the Reporter.—The first two cases seem to have been simply concussion of the solar plexus, without rupture of peritoneum, and recovery without peritoneal inflammation. They are examples of a class of injuries the symptoms of which, though they are characterized by profound shock, disappear in a few hours to be unattended by subsequent mischief. Mr. Pollock (on Injuries of Abdomen, *Holmes' System of Surgery*, vol. ii. p. 619–23) relates similar cases from *St. George's Hospital Reports.* The condition of Cases III. and IV. rapidly became alarming. Although the external manifestations of injury were but slight in Case IV., and none in Case III., there must have been a rupture of the peritoneum (probably parietal portion) and localized peritonitis.

The practical teachings to be obtained from the above, are that trifling blows to the yielding abdominal walls must be considered with care and treated with caution. We should not, however, despair when the gravity of the symptoms point to the most formidable injury. Contusions of the abdominal walls are more severe than of most other parts of the body. This is due to the coverings of the abdomen having less power to resist blows, and enveloping a large serous surface in intimate connection with the solar plexus of nerves.

The theory has long been held that sudden death may follow a blow on the abdomen without any perceptible organic lesion being detected on dissection, and Woodman and Tidy (*Forensic Medicine*, p. 1029) refer to cases in which persons have been convicted of manslaughter, though no morbid appearances were detected on *post mortem* in the bodies of those whom they were supposed to have killed. They claim that in such cases of sudden death, the solar plexus or semilunar ganglion is injured. Guy (*Forensic Medicine*, p. 376) says "contusions of the abdomen may produce sudden death by shock, rupture of epigastric artery, or peritoneal inflammation." Similar views are held by Beck (*Med. Jurisp.*, p. 282); Dean (*Med. Jurisp.*, p. 231); Wharton and Stillé (*Med. Jurisp.*, p. 861); Taylor (*Med. Jurisp.*, Amer. ed. by Reese, p. 338). Travis, Alison, Watson, Cooper, and others, also speak of blows on the pit of the stomach producing sudden death without visceral lesion. Pollock (*op. cit.*) has carefully investigated the cases brought forward to establish this popular theory, and shows that the facts related in them do not justify their view. Woodman and Tidy refer to the following cases: Regina *v.* Laws, Norwich Lent Assizes, 1854; Rex *v.* Jones, Warwick Summer Assizes, 1831. Mr. Wood (*Medical Gazette*, vol. xliv. p. 213) reports a case which Dr. Taylor considers an "unequivocal instance" of sudden death from a blow on the epigastrium. Pollock quotes this case in detail, but rejects it; the man had been engaged in a pugilistic encounter for some time, had received repeated blows and bruises previous to the one in the pit of the stomach, and was intoxicated. These formed three elements of physical exhaustion rather than sudden death from a blow in pit of stomach. The post-mortem examination revealed contusions from the effect of the repeated blows, and the meninges and brain were congested as the result of intoxication. Mr Poland (Prize Essay on Injuries of Abdomen, quoted by Pollock) relates a case of a woman in advanced pregnancy. She had received repeated blows inflicted by her husband with a cod-fish for several minutes; no lesion was found. Her husband was tried and convicted of murder in Norfolk Circuit Court, at Cambridge, in 1835. Another case is quoted by Poland, of a man killed in a pugilistic encounter, and his antagonist convicted in Central Criminal Court, August, 1841. In Sir Astley Cooper's case, the exhaustion and heart disease were sufficient to account for the sudden death, and he only received the case second-hand.

Those cases, as Pollock has suggested, were reported before pathological changes were observed as carefully as at present, and pre-existing disease may have been present in some, and many of them have been in physical combats where exhaustion and excitement furnish an important element in the cause of death. I have consulted many of the American and English journals of the last twelve years, and have been unable to find a case where sudden death has resulted from a blow to the abdomen without any visceral lesion being detected by careful dissection. Many of the medico-legal authorities referred to above refer to the same notes that Pollock rejects. They state that the cases are numerous, but it seems rather remarkable that they should select those to establish their theory, which have been shown to be of questionable nature, and that no case should have been mentioned since 1854. The recovery of the four cases recorded in this paper, in two of which peritonitis had set in, seems to support the view held by Pollock. At least further carefully conducted autopsies are necessary before the old theory—that sudden death may result from a blow to the abdomen without any perceptible organic lesion—can be considered demonstrated beyond reasonable doubt.

VIENNA GENERAL HOSPITAL.

(Service of PROF. BILLROTH.)

RESECTION OF THE PYLORUS FOR STENOSIS.

(Specially reported for THE MEDICAL NEWS.)

PROF. BILLROTH, upon the 3d of August, performed the second recorded pyloric resection for stenosis of non-malignant origin. The first operation, it will be remembered, was performed by Rydygier for stenosis following gastric ulcer.

Three weeks before the operation Prof. Billroth's patient swallowed a quantity of caustic soda, which resulted in the production of stenosis of the pylorus. Food was regurgitated whenever ingested, and the evidence was complete that it could not pass the pylorus.

An abdominal incision from ten to eleven cm. in length was made, and the constricted pylorus was removed, the exsected portion measuring about ten cm. in length, and possessing an irregular quadrilateral form. The lower portion of the oblique incision through the stomach was secured in the so-called "oc-

clusion suture" by six deep and ten superficial silk sutures. The length of the "occlusion suture" was about ten cm. The upper portion of the oblique incision was thus converted into a circular wound whose lumen corresponded exactly with that of the adjoining portion of the duodenum. The gastric and duodenal walls were then neatly united and the external wound closed.

The hemorrhage, during the entire operation, was trifling and easily checked. The patient evinced very little shock, although the operation lasted one and one-quarter hour.

The same sponges which were used for the removal of the contents of the stomach were employed in performing the "toilette" of the peritoneum.

The patient received upon the day of the operation, milk; the next day, soft food; and before the sixth day, meat was ingested.

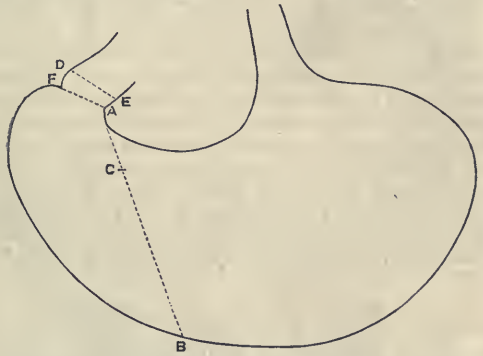
No untoward symptom occurred until the sixth day after the operation, when evidence of peritonitis was given, and the patient died.

The autopsy, made upon the following morning, showed that six stitches in the "occlusion suture" had given way, allowing the contents of the stomach to escape into the abdominal cavity. Small abscesses had formed around each of the stitches that had given way. The usual lesions of acute peritonitis were also noted.

It is supposed that the small abscesses about the stitches were of septic origin, due to the employment of the same sponges for removing the stomachic contents and cleansing the peritoneal surface of the "occlusion suture."

The result in this case is regarded with profound regret by Prof. Billroth, and his first assistant Dr. Wölfler, for if the patient had recovered, it would have established the feasibility of the operation.

The appended diagram will serve to convey an idea of the steps of the operation.



A B. Incision, oblique, through stomach.
D E. Incision through duodenum.
A F. Seat of stricture.
B C. 10 cm. length of "occlusion suture."
A C. Free portion of oblique incision through stomach in circumference.
D E. The circumference of duodenum.

MEDICAL PROGRESS.

EXTIRPATION OF THE CANCEROUS UTERUS.—DR. A. N. SOLOVIOFF, of Moscow, records (*Mediz. Obozr.*, Jan. 1882) his third case of extirpation of the uterus for carcinoma of the cervix, in a patient aged 53. The operation was performed through the vagina. The uterus having been brought down by means of Museux's forceps, the cervix was separated from the surrounding parts, and then Douglas's pouch was laid open. The anterior peritoneal *cul-de-sac* was not opened; the operator cut off, by means of scissors, the whole of the mucous membrane and the greater part of the muscular wall, leaving a thin stratum of the latter, with the serous covering *in situ*. The broad ligaments were then divided, some vessels were tied, and a drainage-apparatus (four Nélaton's flexible catheters sewed together) was introduced into the opening in Douglas's pouch. On the seventh day after the operation, the drainage-tube was removed. On the fifteenth day, the patient was up. Her recovery was rather slow. This is the second time the author has operated through the vagina, which method he prefers to the high (or laparotomic) operation, finding the low extirpation technically easier and less liable to such complications as shock, or accidental wounding of the bladder or ureters. The high operation he regards as indicated only when the uterus is too large to be removed through the posterior or anterior peritoneal *cul-de-sac*, or when there exist adhesions of the womb and degeneration of lymphatic glands (*Mediz. Obozr.*, Oct. 1881, p. 516). The author gives the reasons which led him to perform total extirpation of the womb, though the cervix alone was affected. The researches of Drs. Ruge and Veit have shown that in cases of cervical cancer the epithelium of the body of the uterus also degenerates very early. Microscopic examination of the mucous membrane of the body of the organ in the author's case fully confirmed the statement of Ruge and Veit. Dr. Solovioff belongs to the most ardent advocates of Freund's operation, and even holds that total extirpation of the uterus is the only rational procedure in the treatment of uterine cancer.—*London Medical Record*, July 15, 1882.

EARLY OPERATIVE TREATMENT OF STRUMOUS JOINT-DISEASE.—MR. J. GREIG SMITH summed up his remarks in opening the discussion on this subject at the recent meeting of the Section of Surgery of the British Medical Association, as follows:

1. Strumous disease starts either as a synovitis or as a medullitis, and requires different forms of treatment as it is one or the other.

2. In synovio-arthritis, while recommending the use of such measures as elastic compression over cotton-wool, counter-irritants, and functional rest, he believes that a systematic use of passive motion is beneficial.

3. In medullo-arthritis, absolute rest in plaster o Paris he believes to be, on the whole, the best form of treatment—better than extension, and better than counter-irritants and other means.

4. If there be no signs of improvement after a few weeks' use of such treatment, he believes that we ought to step in and operate. In synovia-arthritis, the most generally useful plan would be, to make large incisions into the joint, peeling the granulations off the articular cartilage, and removing as much of the pulpy material as possible, and freely draining. In medullo-arthritis, we ought to remove the inflamed marrow from the inside of the bone along with the trabeculæ, and endeavor to fill the cavity with blood-clot. In both cases, he would operate antiseptically.

5. If these means fail, then excise; but excise early. —*British Medical Journal*, August 26, 1882.

YVON'S TEST FOR THE PURITY OF CHLOROFORM.—The test recently proposed by M. Yvon for the purity of chloroform (see THE MEDICAL NEWS, March 4, 1882, p. 244), has been subjected to a critical examination by several English chemists, and is condemned for the following reasons:

1. The test is too rigorous, in that it does not permit of the presence of the small proportion of alcohol which experience has proved necessary for the preservation of chloroform.

2. That any sample of chloroform, however impure,

can be made to answer to the test by merely agitating it with sulphuric acid.

3. That all chloroform manufactured, previous to the addition of alcohol, will stand the test, although it may not pass the tests ordinarily prescribed.

4. That the chloroform purified by M. Yvon's process, by agitation with an alkaline solution of potassium permanganate, is certainly not pure, even judged by the crude test of the odor alone.—*Detroit Lancet*, September, 1882.

Resection of the Hip-joint.—Mr. George Cowell reported at the meeting of the Section of Surgery of the British Medical Association his experience in sixty-five cases of excision of the hip, in which his percentage of deaths amounted to ten per cent. His conclusions are:

1. Resection should be restricted to cases where there is distinct grating in the joint, accompanied by either pain or profuse suppuration, or failure of health.

2. It should be performed without loss of time, as soon as these conditions are recognized.

3. It is inadmissible in patients over eighteen years of age. All three of my older patients died with more or less prolonged suppuration, and without the slightest attempt at repair. I have never seen an adult patient recover from excision of the hip.

4. The younger the patient (my youngest patient was three and a half) the more satisfactory the result, and the more rapid the repair.

He now performs the operation antiseptically, and always removes the great trochanter with the head of the bone. By not postponing the operation, the acetabular mischief is usually slight. Both ends of the wound are closed with two silver sutures, a tube being inserted so as to keep the centre of the wound, opposite the acetabulum, open. He prefers Bryant's splint, and fixes the limb operated upon one inch shorter than the other. This extension is a matter of great importance, as he is convinced that the muscular contraction forcing the shaft of the femur against some part of the acetabulum is a frequent source of subsequent failure, and of undeserved discredit of the operation. In the last few cases, when possible, he has placed the children for the first few weeks in the prone position (face downwards), so as to avoid soaking the bandages with urine. He has tried this plan for too short a time to express any positive opinion with regard to it; but it answers its purpose exceedingly well, and is marvellously tolerated by the little patients.—*British Medical Journal*, August 26, 1882.

Purulent Ophthalmia Cured by Iodoform.—Dr. Dujardin reports the case of a child, eight monts old, who has been suffering for five days from purulent ophthalmia. Both corneæ were grayish throughout, and on the point of ulceration. The eyelids were constantly closed, and presented a truly enormous erysipelatous swelling; pus escaped in abundance, unmixed with tears. The general condition was bad; face pale; complete loss of sleep and appetite.

At first, according to routine practice, a two per cent. solution of nitrate of silver, neutralized with salt-solution, was applied, and then washed freely with pure water. The result was not good; the everted eyelids presented whitish escars, produced by the cauterization; both corneæ showed well-defined opacities, probably caused by the injurious action of the nitrate of silver; the conjunctival suppuration remained quite as abundant as before, and the swelling of the lids underwent no change in spite of the use of iced water compresses. Under these circumstances it was almost despaired of a successful issue, but he resolved to try the insufflation of iodoform so strongly recommended, and dusted the powder all over the conjunctival surface of the lids. The following day an improvement was noticeable; the purulent discharge had decreased considerably, and the eyes began to water, which he regarded as a very favorable symptom. He continued the application of iodoform. During this time the little patient took broth and Malaga wine. The purulent secretion then entirely ceased, the tears ran freely, the corneæ returned to a better state, becoming more transparent; the superficial opacities, due to the use of the nitrate of silver, gradually disappeared. Eight days from the commencement of the treatment the child was out of danger. He sent him back to his parents at Roubaix, with only a small opacity remaining in each cornea, which will, doubtless, disappear in a short time.—*Ophthalmic Review*, September, 1882.

Antidiphtheritic Inhalation.—Some years ago, Dr. H. Hagar recommended a mixture composed of

Carbolic acid,	10 parts.
Alcohol,	10 "
Water of ammonia,	12 "
Distilled water,	20 "

as an excellent inhalation in catarrhal affections. It was directed to be used thus: A small wide-mouthed bottle was to be filled one-third with the liquid; then a sufficient quantity of cotton was to be introduced to just soak up all the liquid. The bottle was to be well stopped. In coryza, incipient catarrh, or similar affections, the inhalation through the nostrils of some of the vapor of the compound was found to be of the greatest benefit.

The same author now recommends a still stronger compound, to be made from

Carbolic acid,	10 parts.
Oil of turpentine (or oil of eucalyptus),	5 "
Water of ammonia,	12 "
Alcohol,	20 "

A small quantity of this is to be dropped into a small wide-mouthed bottle half filled with cotton or asbestos, and the bottle well stopped. After a few days, a little more may be added, until a strong odor is given off when the bottle is opened.

A physician to whom Dr. Hagar recommended the use of the compound thinks that it prevents the spread of diphtheria, since, in five families, in each of which one case of diphtheria had become developed, its further spread was arrested, apparently through the use of the antiseptic inhalation. In another family, a second child was taken with the disease; but the child could not be coaxed to inhale the vapor. The inhalations should be as full and deep as possible. In some cases of coryza, it has been used with most excellent effects.

Should the odor of oil of turpentine be too offensive to any person, oil of eucalyptus may be substituted for it.—*Cincinnati Lancet and Clinic*, Sept. 9, 1882.

An Unusual Relation Between the Placenta and the Membranes.—In the September number of the *New York Medical Journal and Obstetrical Review*, Dr. Henry J. Garrigues, of New York, describes a very remarkable relation between the membranes and the placenta. The placenta measured twenty centimetres in diameter, the cord sixty-four centimetres in length, and both were of normal thickness. The cord was inserted centrally. The membranes which had contained the child did not adhere to the edge of the placenta, but started from the point of insertion of the cord on this organ. Measured in a flaccid condition, hanging down around the cord, this bag was forty-one centimetres long. It was easily separated into two layers. The inner layer was covered with the epithelium characteristic of the amnion, a single layer of flat polygonal cells, which were in a state of fatty degeneration, as proved by numerous oil globules found in their interior. The outer layer consisted only of con-

nective tissue, which, in some places, contained a few round or oval cells, and many fat drops. In other places some loose shreds were found on the outer surface, which showed a greater number of similar cells. At the placental end of the cord the sac was seen to form a kind of triangular mesentery, embracing the first eleven centimetres of the cord, and attached to the sac to a similar extent. The two layers forming this fold were not united, so that the finger could be pushed in between them up to the cord; but at the lower end (*i. e.*, nearer to the fœtus) they grew together, so that a pouch was formed between the "mesentery" and the cord, admitting half the length of the index. At the placental end of the cord there was found in the interior a small clear vesicle of the size of a pea (the umbilical vesicle). The placenta presented the common shining, smooth fœtal surface, and rough maternal surface. The edge looked ragged, as if something had been torn from it, and in one place even a small, square piece of membrane about two centimetres in either direction was found attached to it. This membrane had no epithelium, and was composed of an inner layer of connective tissue, and an outer layer containing many round and oval cells. From the fœtal surface two membranous layers could be dissected off. The most superficial was exceedingly thin, the deeper one comparatively thick, and bound by isolated fibres to the placental tissue. The fœtal surface had no epithelium. The chief point of interest was that the sac in which the fœtus was placed, and which contained the amniotic fluid, was not attached to the circumference of the placenta, but to its centre, all around the insertion of the cord.

Microscopical examination showed that this sac was composed of the amnion and the chorion, but had only scant remnants of decidua attached to it here and there. On the other hand, the portion of membranes found attached to the edge of the placenta was composed of decidua and chorion without amnion, and the fœtal surface of the placenta had no amniotic epithelium. Dr. Garrigues supposes, therefore, that the placenta all around was separated, after the birth of the child, from the decidua, which remained attached to the interior of the womb. Secondly, that the amnion and the chorion together formed a fold from the circumference to the centre of the placenta, which fold on one side was open, and formed the meso-cord described. Such a folding was, perhaps, brought about by accumulation of fluid between the chorion and the decidua after the formation of the placenta. At first he supposed that the amnion alone partook of the folding; but then we should find, he adds, on the sac surrounding the fœtus, the line where the chorion had been torn, and there was no trace of anything of the kind. He thinks, therefore, we must conclude that the chorion remained close to the amnion all the way, and was folded with it so as to cover the fœtal surface of the placenta twice, as well as the amnion. This supposition is corroborated by the fact that two layers could be dissected from the fœtal surface of the placenta. The outer one was very thin, and this he took to be the chorion; the inner was thick, and this he explains as being the two layers of amnion grown together by their epithelial surfaces.

INGUINAL HERNIA OF THE OVARY.—PROF. ROSATI (*Jour. de Med. et de Chirurg. Prat.*, July, 1882) reports a case of inguinal hernia of an ovary resembling a strangulation of the intestine, where a removal was followed by restoration to health. A Florentine woman, forty-eight years of age, presented herself to his surgical clinic (*Presse médicale belge et Sperimentale*) for relief from a tumor situated in the left inguinal region, and about the size of a large potato. This tumor, rather hard and somewhat nodular, offered slight fluctuation at the level of greatest prominence. There was also a painful spot aggravated by pressure, the pain radiating to the umbilicus and epigastrum. Reduction was easy, but the tumor reappeared immediately upon removal of the pressure.

According to a statement of the patient, her mother had been aware of the existence of the tumor from her birth. At first very small; it attained the size of a walnut.

The patient had menstruated regularly since fifteen years of age, and has been three times pregnant. The first and third pregnancies terminated normally, the second in an abortion at the third month. It is interesting to note that during the two normal pregnancies, and beginning with the seventh month, the tumor passed up into the abdomen and remained there until delivery, permitting the patient to lay aside the bandage she was accustomed to wear.

Finally, a few days previous to the consultation, and just at the onset of menstruation, the patient was seized with a chill, accompanied by severe headache and a bad cough; the entire abdomen became painful, and in a short time vomiting supervened.

Prof. Rosati diagnosticated the malady as one of irreducible, congenital, inguinal hernia of the omentum, and prescribed rest in the recumbent posture, low diet, morphia internally, and application of ice to the seat of pain. But after a few days the vomiting became more pronounced, the retention of feces was complete, and the surgeon had recourse to the operation for strangulated hernia. Arriving at a point of fluctuation which he supposed to be the hernial sac, he incised it with care and gave exit to a sticky fluid. The other prominences not communicating with this one were likewise incised.

The pedicle of the tumor, extending up to the abdominal opening of the inguinal canal, was enucleated, and the operator recognized that the tumor was riddled by little cysts. Certain by this time that he was dealing with the left ovary, he severed the pedicle between two ligatures of catgut, inserted a drainage tube and united the edges of the wound. The recovery was complete in a few days. Microscopic examination of the specimen confirmed the belief that it was ovarian.—*Cincinnati Lancet and Clinic*, August 26, 1882.

AN ACCIDENT OF LABOR.—The frequency with which the compression of the cranium, during the passage of the fœtal head through a small pelvis, causes serious injury to the cerebral substance is well known. It is not probable that the skilful use of forceps increases the amount of damage; it is possible, although difficult to prove, that thus the injury may sometimes be lessened, but whatever be the force of mechanism by which the fœtal head passes through a narrow aperture, compression and damage there must be, in proportion to the contraction of the orifice. The fact of the injury to the cerebral tissue which results is strikingly illustrated by the discovery of Ruge that brain tissue may be found in the circulating blood in these cases, a fact which may also explain some other symptoms occasionally observed soon after birth in cases of difficult and instrumental labor. Ruge recorded three such cases, and a fourth has recently been placed on record by Dr. Paolo Negri of Milan. In this case, however, the fœtal head was compressed in the uterus and not in the pelvis, the presentation being transverse. The woman was small of stature, only four feet six inches high, with old rickety deformities. Her first labor had to be terminated by embryotomy; in the second and third pregnancies labor was induced in the eighth month. In the fourth, she had gone to the full time and the arm presented. Several

attempts at turning were made without success, the membrane having ruptured; ultimately version was effected under chloroform, but the child had been dead some time. Its heart was carefully removed, the vessels having previously been tied. In the left auricle and left ventricle there was but little blood, but in the right auricle there was a quantity of liquid blood, mixed with numerous soft whitish fragments of tissue, similar in appearance to cerebral tissue. A drop of blood, mixed with a drop of a saline solution, showed under the microscope a considerable number of well-formed nerve cells, while minute capillaries were found in the whitish fragments. — *Lancet*, August 26, 1882.

Removal of the Superior Maxillary Nerve for Neuralgia.—At a recent meeting of the New York Society of German Physicians, Dr. Gerster showed a patient who had suffered from facial neuralgia for many years, probably induced by extreme degrees of heat and cold to which the man had been exposed by plying his trade as an oven-builder. In 1877 Dr. Mott divided the nerve, but the pain returned after a short time. In 1878 Dr. Hassloch gave large doses of salicylic acid and quinia, with but temporary benefit. Subsequently Dr. Weir brought about a remission of three months by subcutaneous injections of $\frac{1}{96}$ gr. of aconitia, repeated every two hours. Dr. Gerster then proposed and performed Langenbeck's osteoplastic section of the superior maxilla, with displacement of that bone and removal of the nerve. Two incisions were made—the first along the lower border of the malar bone, beginning in the nostril and terminating at the middle of the zygoma; the second beginning at the nasal process of the frontal bone, following the lower margin of the orbit and joining the first incision on the zygoma. The masseter was dissected from its attachments, and the soft parts were separated from the bone as far as the pterygo-palatine fossa, and, by means of a key-hole saw, the superior maxillary bone was divided parallel to the hard palate and into the nose. The infra-orbital nerve was now exposed in the line of the upper incision, and cut through at its exit from the infra-orbital foramen; after this the eyeball was pushed upward, and, the key-hole saw being introduced through the infra-orbital fissure, the zygomatic arch was cut through. The floor of the orbit was now carefully chiselled through, care being taken not to injure the lachrymal duct, and, by introducing a lever into the cut in the malar bone, the exsected piece of the bone was turned out, hinging upon its soft attachment to the nasal and frontal bones. Thus, the nerve glided out of the infra-orbital canal, and was cut away at the foramen rotundum. The wound was now disinfected with an eight per cent. solution of chloride of zinc, the bone was replaced, superficial sutures were applied, and, after six weeks the wound was healed. This method was preferable to the one practised by Carnochan, as it gave ample room for manipulation, and a very clear insight.—*New York Medical Journal*, September, 1882.

Operative Treatment of Ozæna.—Ozæna is often due to a contraction of the nasal cavities, whereby the free passage of air and thorough washing out of the secretions are prevented. In order to overcome this, Volkmann removed, with a chisel, a portion of the middle turbinated bone in two young girls suffering from this affection. Great improvement resulted.—*Deutsches Med. Woch.*, August 19, 1882.

Some Recent Developments in Antiseptic Surgery.—To those whose acquaintance with antiseptic surgery dates back to the time when the carbolic dressing of Lister was first introduced, and can remember the rigid ritual enjoined in its use, the last substance added to the surgeon's armamentarium must be the source of some quiet amusement. It appears that, about two years ago, a man applied to Dr. G. Neuber, assistant in the clinic of Prof. Esmarch in Kiel, with the story that, eight or ten days earlier, he had suffered a severe accident to the forearm, which had resulted in extensive laceration of the soft parts, rupture of the wrist-joint, and fracture of both bones of the forearm. The first dressing applied to this severe compound and complicated fracture was a thick coating of mould from the moor on which the man was at work. After burying the limb in this, a rough wooden splint was applied. When, ten days later, the man came into Kiel, he appeared to be in good general health; and, after the astonished surgeons had thoroughly removed the whole of this primitive dressing, they found that the wound was free from suppuration—in some parts already united by first intention, in others granulating in a satisfactory manner. Struck by this brilliant result, Dr. Neuber proceeded to investigate the antiseptic qualities of turf-mould. These qualities were already being recognized in other quarters. It had been found that the turf, which is of a remarkably fibrous and friable character, acted as a powerful deodorizer of fecal and other like offensive substances. A series of experiments in the use of the mould as a surgical dressing were made, and the experience gained may be thus summed up. The turf-mould reduced, as we gather, to a powder, is enclosed in gauze bags which have been thoroughly washed in carbolic acid solution. The bags are made of two sizes, and the mould in the smaller is mixed with iodoform in the proportion of 2.5 per cent.; the mould in the large bag is saturated with a solution of carbolic acid (5 per cent.). In applying the dressing, the wound is first washed with carbolic or with chloride of zinc lotion, or powdered with a little iodoform. The small bag is then placed over the wound; over that a large bag is adjusted; and both are retained in place, and an equable pressure kept up by a gauze bandage. The dressing was used by Prof. Esmarch in fifty-five cases, among which were included seven resections and osteotomies, five amputations, twelve extirpations of tumors, and two herniotomies. The results were most satisfactory. The only death was in a case of advanced tabes dorsalis, where the operation of nerve-stretching was followed by pyæmia. In thirty-one cases there was no fever at all; in only five cases was it necessary to remove the dressings, owing to either local or general disturbance; and, as a rule, they were left in place for a fortnight. The advantages claimed for the mould are, briefly, that its absorbent power is so great that wounds remain perfectly dry under its use; that it absorbs the products of decomposition, and probably checks their formation; that the pads are very soft and elastic, easily adapting themselves to the surfaces of the limbs and trunk; and that, finally, turf-mould affords the cheapest known antiseptic, since it costs only about one-ninth as much as carbolic gauze (Listerian) dressings. In a second communication, Dr. Neuber gives the results in a second series of cases, among which were instances of ovariotomy, hysterotomy, and operations for floating kidney. This second series of seventy-eight cases resulted in but three deaths, due respectively to tetanus, to delirium tremens, and to gangrene of the leg after resection of the knee in a "bleeder." Where it is proposed to leave the dressing undisturbed for a fortnight or more, Dr. Neuber applies glass bandages externally.—*British Medical Journal*, August 26, 1882.

Hystero-laparotomy during Pregnancy from a False Diagnosis.—Reimann (*Centralb. f. Gynecol.*, No. 15, 1882) reports the case of a Jewess, aged thirty-two

with a tumor which the attending physician diagnosed as ovarian. At the first examination, he thought he detected signs of pregnancy, but later could not find them. A surgeon was called to operate, and after careful examination did so, supported by two statements, first, that of the woman that she had had no connection with a man for over a year, and second, that of the assistants, who (falsely) stated that the physician had introduced a probe, and found the uterus not enlarged. The operator made a small abdominal incision, introduced two fingers, and as there were no adhesions, punctured the supposed tumor, when, to his astonishment, there was a gush of liquor amnii, and on introducing the finger, parts of the child in utero could be felt. There was no longer any doubt. The uterus was laid open, its contents removed, and the wound sewed up. The child, eight months, lived about fifteen minutes. The mother died on the third day of peritonitis. The case has been brought to trial by court, and is not yet ended.—*American Journal of Obstetrics*, September, 1882.

ANTAGONISM BETWEEN SYPHILIS AND VACCINIA.—In the *Gazette Hebdomadaire*, M. POLIN, a public vaccinator in one of the military districts, states that in nearly every instance in which a child suffers from hereditary syphilis, vaccination will fail.

ERGOTINE IN TYPHOID FEVER.—The treatment of typhoid fever by the subcutaneous injection of ergotine, as recommended by Dr. Dubonè, continues to be noticed in *Le Journal de Médecine et Chirurgie*. The last case described is of a young woman, three to four months pregnant, in whom the treatment was begun on the eleventh day of the disease, when there was much tympanites, diarrhœa, bronchitis, and dyspnœa, and when continuous delirium had given place to semicoma. The morning temperature was 104° F. Ten centigrammes of ergotine were injected daily for six days. The first injection was followed by a copious general papular eruption of the size of a millet seed. The temperature fell to 101.5° F., and did not again rise above 103° F. The other symptoms underwent corresponding amelioration, and the temperature became normal on the seventeenth day of the disease.

Four days after the discontinuance of the ergotine the patient aborted without any unfavorable symptoms. The fact that the abortion in this case took place so long after the omission of the ergotine, and the history of another case in which one and a half to two grammes of ergot were administered daily for two weeks to a pregnant woman without causing miscarriage, seem to confirm the harmlessness of this drug to persons who are pregnant.—*Boston Medical and Surgical Journal*, August 31, 1882.

SUDAMINA IN TYPHOID.—M. ALBERT ROBIN has examined the liquid of sudamina in a case of typhoid fever, in which the eruption was so abundant the vesicles were confluent, and formed bullæ of considerable size, some of them being as much as a centimetre in diameter. More than three grammes of liquid were collected from them. It was transparent and colorless, but on standing, a deposit formed, consisting of whitish flocculi, and at the same time the liquid became opalescent. It had a slightly acid reaction, and a strong, unpleasant odor. The microscope showed only a number of fine globules of fat and some epidermic cells. It contained neither albumen nor sugar, and was not rendered opaque by the addition of alcohol. No uric acid could be discovered in it by the murexide test. An analysis showed that it contained a considerable quantity of chlorides, but no trace of sulphates or phosphates; the proportion of water was 982, of solid matter 18, per 1000: the solids consisting of 14 parts of organic and 4 of inorganic substances. Hence the amount of organic material eliminated by the perspiration in typhoid must be regarded as considerable.—*Lancet*, August 26, 1882.

HERPES OF THE HANDS AS A MENSTRUAL ERUPTION.—JANOVSKY and SCHWING (*Centralb. f. Gynecol.*, No. 17, 1882) report the case of a woman, unmarried, thirty years old, who had always had difficult menstruation from her fourteenth year; in 1873 had inflammation of the internal genitals, after which, to 1880, she was perfectly well except a deep-seated pain in the right side. At the end of 1880, patient came under author's treatment on account of renewed, severe difficulty of menstruation. Right-sided ovaritis was diagnosed and greatly benefited by treatment. In April, 1881, on the second day of menstruation, a skin affection began on both hands, accompanied with sharp burning and itching and slight constitutional disturbance. On the palmar surface of both hands, especially the left, the skin was red and swollen. This was limited strictly to the palmar surface and bounded by the wrist-joint, the tips of the fingers, and the middle line between palmar and dorsal surfaces. The diffuse swelling lasted one and a half to two days. On the then paler skin little vesicles appeared, as large as pin-heads, isolated, or only in parts confluent. Gradually they filled up, their contents became purulent, they dried into crusts and dropped off. The whole process, which was quite severe, lasted a month. Four menstruations passed without its recurrence. In September it came on again, much lighter, again more marked on the left hand. This lasted two weeks. At the next menstruation only the left hand was affected. For five periods it remained away, and in May of this year again appeared, and again especially on the left hand.

The eruption is a herpes. There was no herpes of any of the membranes and no neuralgia accompanied it. The authors have seen many exanthemata connected with menstruation, and especially a symmetrical erythema papulatum on the flexor surface of the upper and lower extremities, and in this connection they consider the present case of interest.—*American Journal of Obstetrics*, September, 1882.

THE SUBCUTANEOUS ADMINISTRATION OF CATHARTICS.—A. HILLER has made a number of experiments, with a long list of cathartics, and concludes that the hypodermic method possesses no advantage over the internal administration of cathartics, either in the dose required, the time required or in the avoidance of disagreeable symptoms.—*Centralb. f. die Med. Wissen.*, August 19, 1882.

DISLOCATION OF THE CERVICAL VERTEBRÆ, WITH SPONTANEOUS REDUCTION, AND FRACTURE OF THE STERNUM.—At a recent meeting of the Clinical Society of Maryland, DR. MICHAEL exhibited specimens from a case of dislocation of the cervical vertebræ with spontaneous reduction and fracture of the sternum without external manifestation, in the same patient. The subject of the injury was an Italian seaman, æt. 40, who fell into the hold of a vessel. Paralysis ensued below the level of the nipple. There was intermittent priapism persisting until near the end. Nothing was discovered along the spine to indicate lesion there, but there was evidently a grave lesion of the cord. There was no tender spot on the vertebræ, but pain was complained of in the cervical region. Respiration was carried on entirely by the diphraghm. Death ensued on the third day. *Post-mortem:* No lesion found up to cervix. There had been a dislocation of the fifth on the sixth cervical vertebra which had been reduced in the movements of the patient. The anterior common

ligament was disconnected from the sixth cervical vertebra, the ligamenta subflava were destroyed; the intervertebral substance between the fifth and sixth vertebræ was entirely destroyed. The cord was inflamed and compressed and its lower part congested. The sternum was found fractured on its posterior surface where the periosteum was ruptured; anteriorly the periosteum was not ruptured. There was no evidence of injury of the sternum during life. The lung had been lacerated and the mediastinum was emphysematous. The urine had to be drawn with a catheter.—*Maryland Med. Journal*, Sept. 1, 1882.

Curious Malformation of the Ureter.—In the *Lyon Médicale* for June 4, 1882, M. Soller reports a remarkable case of incontinence of urine that came under observation in M. Laroyenne's service at the *Clinique des Maladies des Femmes de la Faculté de Médecine de Lyon*. The patient was a girl, eighteen years old, who was found to have a supplementary meatus urinarius, situated below and to the right of the normal meatus. A small catheter could be introduced about 10 cm., and a few drops of normal urine escaped through it, although at the time the bladder was full of urine, which the patient was able to retain. The dropping from the supplementary channel continued after the bladder was emptied with the catheter. A strong solution of fuchsin was injected into the bladder, but the urine which continued to drop from the abnormal meatus was not colored, and analysis showed it to be absolutely normal. The opening was closed temporarily with a catch-forceps, and, on removing it the next day, a considerable quantity of urine escaped, being projected in a jet to a distance of more than 15 cm. In view of these facts, M. Laroyenne diagnosticated an abnormality of the right ureter, which, he supposed, either pursued its course direct to the false meatus, or else bifurcated before penetrating the bladder, and sent a branch to the locality mentioned.—*New York Medical Journal*, September, 1882.

Electrical Stimulation of the Uterus.—The influence of electricity on the uterus, whether empty or gravid, is a point on which authors have made various statements. This difference of opinion may be due to the circumstance that the conclusions have been drawn from the somewhat uncertain field of clinical observation. M. Dembo, in a note presented to the Académie des Sciences by M. Vulpian, has endeavored to decide the question by experiments on animals. His observations at present relate only to the non-gravid condition. In the rabbit direct faradization of the uterus or of one of its cornua causes a contraction at the point to which it is applied, and which extends for a distance of about twenty millimetres, but never reaches the other cornu. If one electrode is applied to each cornu, both can be made to contract in the neighborhood of the poles, but not in the interval between them. Very different, however, is the effect when the application is made to the vagina. If both electrodes are applied to the vesical wall of the vagina, a manifest contraction is produced in both parts of the uterus, vermicular in character, passing from below upwards. If the application be made to the lateral portions of the vaginal wall, a contraction is produced only in the corresponding cornu. Local contractions on the corresponding side can be produced by placing the electrode on certain points in the broad ligament, but the contraction never extends to the whole uterus. It is impossible to produce contraction of the non-gravid uterus by faradization applied through the abdominal wall. The excitability of the uterus of the rabbit was found to vary according to the age of the animal, and according to whether it had borne young or not. That of a young animal is so irritable that manifest contractions are excited by mere exposure to the air, but in old rabbits the uterus is much less susceptible. In some dogs and cats no contraction of the empty uterus could be obtained by faradization, in others slight contractions with distinct pallor were produced. Faradization of the vaginal wall caused pallor of the mucous membrane, and also of the whole uterus, due apparently to contraction of the vessels, but no contraction of the substance of the uterus. Frankenhauser found that stimulation of the aortic plexus caused a manifest contraction of both cornua, and it is highly probable that an analogous nervous plexus is situated in the vesical wall of the vagina. The observations were made on animals under the influence of either chloral or curara.—*Lancet*, August 26, 1882.

Iodoform After-treatment and Permanent Irrigation in Gynecological Operations.—Schucking (*Centralb. f. Gynecol.*, No. 13, 1882) believes that iodoform stands in the first rank as an antiseptic for the after-treatment of wounds in gynecological operations. Its energetic, continued, and yet unirritating disinfective action, its easy application to regions where Lister's method is impossible, the fact that under its use the wounds, especially in plastic operations, may be "left alone" for a long time, all render it an important acquisition to our pharmacopœia. It can never do away with the use of antiseptic methods during operations, or undermine in any degree the necessity of Lister's full process. In all Schücking's cases, Lister's method has been carried out in full, and the wounds were washed with a five per cent. carbolic solution before the application of the iodoform. In three prolapse operations in which the vaginal wounds were extensive, the surface of the wound was brushed with iodoform, and then ten to fifteen grms. of the powder shaken into the vagina and allowed to rest quiet for three days, when irrigation was begun. After enucleation of a large uterine fibroid, the whole wound was stuffed with iodoform and cotton. In a laparotomy, the stump was covered with iodoform, and three to four grms. allowed to get into the abdominal cavity. The patient remained free from fever, and in two weeks left her bed. Other cases show that there is no danger of absorption of the remedy. In some cases the drug was used in the form of suppositories made by the formula of Mikulicz (iodoform 90, solution of gum and glycerine āā 5). These were especially useful in abscesses, cancer of the cervix, etc. The terrible smell of the drug can be entirely covered by tonka bean, or, better, by cumarin, a very small quantity of the latter being sufficient to deodorize a large amount of iodoform. The pulse is slightly accelerated by the use of the drug. In conclusion, too much must not be claimed for or expected of the drug, but with other methods carefully carried out it does us great service.

Schücking has devised an apparatus to make permanent irrigation more simple and more applicable to general practice, where the use of bed-pans, the wetting of the bed, etc., have been almost insuperable objections to it. It consists of a sort of short speculum, closed externally, except three small openings. Through the upper of these passes a finely perforated metal catheter, which lies in the vagina and is connected by a screw to the speculum—through the next a short tube to the interior of the speculum. Both of these join externally, and are connected to the irrigator by rubber tubing. The lower opening has a short tube externally, which is attached by tubing to the drip pail. In this way but little water escapes in the bed. Irrigation is usually begun with solution of carbolic acid, but when this (as is generally soon the case) has to be given up, the au-

thor prefers a ten per cent. solution of sulphite of soda. —*American Journal of Obstetrics*, September, 1882.

EXPERIMENTAL INOCULATION OF SYPHILIS IN THE IRIS AND CORNEA OF THE RABBIT.—Previous experiments by HAENSELL and others have established the fact that the introduction of tuberculous matter into the anterior chamber of the rabbit will cause an eruption in the iris of tubercles identical in appearance with the tubercular growths which occur in the human iris. The author has now (*Von Graefe's Archiv*, xxvii., 3) made similar experiments with syphilitic matter, for the sake of comparison between the two morbid processes.

The cornea and the anterior chamber were inoculated in different experiments with the thin purulent contents of a syphilitic gumma of the sternum, with small portions of mucous tubercles of the anal region, and with similar portions of an indurated but non-ulcerated prepuce. Immediate inflammatory changes occurred in some cases, presumably from the introduction of septic matter together with the syphilitic virus, but the process of the syphilitic infection was clearly traceable notwithstanding; it was most characteristic, however, when these extraneous effects were absent.

Four days after inoculation of the anterior chamber, absorption of the foreign substance was complete, and the eye had apparently recovered its normal state; then, after an incubation of about four weeks a subacute iritis set in with turbidity of the aqueous, ciliary injection, discoloration and swelling of the iris, and posterior synechia; some days later vascular nodules appeared upon the iris, such as are seen in syphilitic iritis in the human subject. In one case, at a later period of the disease, larger nodules formed in the ciliary body; these, on account of their larger size and late appearance, may be regarded as true gummata.

After inoculation of the substance of the cornea the period of incubation was rather longer; at the end of six weeks, when only a slight opacity at the site of the puncture remained, several small vascular nodules began to develop.

Post-mortem examination of the animals some months after the inoculation showed in some cases many small hardish nodules in the lungs and liver, which under the microscope were found to consist chiefly of round cells and larger many-nucleated epithelioid cells, together with a few giant-cells.

The differences observed between the syphilitic process and that which followed the inoculations of tubercle were these: the incubation-period of the syphilitic virus was longer than that of the tubercular, and the whole course of the disease much more chronic in character; the syphilitic nodules were finely vascularized throughout, while the tubercular masses were devoid of vessels; the syphilitic never underwent caseous degeneration, while in the tubercular this constantly occurred.

The products of this syphilitic inoculation were found to be capable of successful inoculation upon other animals.

Attempts to inoculate the anterior chamber of the rabbit with lupus failed.—*Ophthalmic Review*, Sept. 1882.

ACTION OF QUINIA AND SALICYLIC ACID ON THE EAR.—In order to ascertain whether the noises in the ears produced by salicylic acid and by quinine are due to a congestion of the labyrinth, Dr. KIRCHNER has instituted some experiments in the pharmacological laboratory at Würzburg. The noise in the ears is sometimes accompanied by giddiness and deafness, which, usually ceasing when the medicine is discontinued, sometimes persists as a serious malady. Kirchner employed in his experiments rabbits, cats, dogs, and guinea-pigs. His conclusions are that both these agents cause hyperæmia of the tympanum, which may go on to hemorrhage, and that the whole of the labyrinth participates in the congestion. It may become so intense that, if it lasts long, it will cause of necessity an alteration in the nerve filaments, and it may lead to exudation. This congestion he regards as produced by a vaso-motor mechanism. In this conclusion, however, another series of observations made by Weber-Liel and Guder does not agree. They observed carefully the symptoms produced in certain healthy individuals by a moderate dose (fifteen grains) of quinine, and noted, during two hours and a half, a gradual fall in the temperature of the external auditory meatus, corresponding to the diminution in the general temperature of the body. No hyperæmia could be detected in the meatus, the membrana tympani, or the handle of the malleus, either during this period or later. On the contrary, in five cases a slight hyperæmia which existed previously was found to disappear. The subjective noises in the ears come on at the end of an hour or an hour and a half, and continue for ten or twelve hours, while the deafness comes on one or two hours later than the tinnitus, and is greatest at the time that the general temperature of the body is lowest. Similar experiments were made with salicylic acid. Four or five grammes of salicylic acid caused a diminution in the temperature of the external auditory meatus, which falls in the course of two or three hours to 95°. No indication of congestion could be discovered, and, as in the case of quinine, previous hyperæmia became lessened. Noises in the ear came on later and lasted longer than in the case of quinine. The deafness is very marked, and continued in some instances for several days, and in some cases, in which there existed previous ear disease, the loss of hearing was more prolonged, enduring in one case for nine months. In more than half the cases giddiness came on a little after the subjective symptoms. Comparing the effects of salicylic acid and quinine, it appears that the former causes a less considerable depression of temperature and a more prolonged diminution in hearing. It is difficult, therefore, to ascribe the aural effects either to congestion or to anæmia, and if these observations are reliable, it would seem to be due to a primary nervous influence.—*Lancet*, Aug. 26, 1882.

THE TREATMENT OF INTUSSUSCEPTION.—In the September number of the *New York Medical Journal and Obstetrical Review*, DR. W. R. GILLETTE, Physician to Bellevue Hospital, relates a case of intussusception in a child nine months old, relieved by injections of water, the administration of chloroform by inhalation, and manipulation of the tumor felt through the abominal wall. This, he states, is the third case of intussusception in infants which he has seen, and which he has been able to reduce by these means. He thinks that these cases, from the philosophy of their condition, and the necessary measures for relief, are best managed in the way indicated. In two other instances, in which he saw and advised this treatment, reduction was utterly impossible under the other methods tried. The children in each of these cases were held while struggling, and the injections forced into them against all voluntary and involuntary efforts which they could make. He deems the administration of chloroform almost absolutely necessary in these cases. The reason is not difficult to find, inasmuch as, while it gives us such perfect control of the patient, it also eliminates the element of muscular spasm. Moreover, massage is a powerful adjuvant to the hydrostatic pressure of water in these cases. In the first two cases the obstruction was not overcome until massage also was employed.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

SEA-BATHING.

ANY one having the least acquaintance with life at the sea-coast feels quite competent to guide himself, and to advise others, concerning sea-bathing. This general confidence of judgment is by no means justified by the results—for every year lives are lost, and the foundation laid for future ill-health, by injudicious resort to sea-bathing. A sad illustration of this fact was recently narrated to us by an experienced physician practising at a sea-coast summer resort. A delicate boy of eight was sent by his physician from the interior to the coast to be braced up by contact with the ocean waves. On the evening of the arrival of the party with the child at the sea-shore, he was taken into the ocean, notwithstanding the temperature of the water was down to 47° Fahr. The child was violently opposed to the bath, but, notwithstanding his shrieks and protestations, was immersed repeatedly. When taken out of the water at last the poor boy was blue and cold, and presently became cyanosed; his pulse grew feeble and irregular, his respiration shallow, and reaction failed to come on, death ensuing in a few hours.

Although the instance just related is an extreme one, it is certain that many cases occur in which the reaction from the bath is ineffectual, latent diseases excited into activity, and various morbid states induced. It is equally certain that great good is accomplished by the right use of sea-baths. It is, then, most desirable to have a clear conception of the physiological effects of sea-bathing, of its limitations, and of the rules to be followed in applying such a remedy.

Without entering into details which possess no novelty, it may be said that a sea-bath is a cold-bath, plus the influence of the place, the air, the shock, etc. To retire to the sea-shore is to cut loose from accustomed associations, and to create new ones under novel conditions. At the sea-shore the air is more stimulating, and the animal sense of existence—the mere delight of life and being—is enhanced. The out-door amusements, the stimulating air, ocean pleasures, increase the appetite, and the power of digestion and of assimilation grows correspondingly. Oxidation in the organism is more rapid and efficient, and hence the forces of life in all directions receive a new impetus. Such conditions are most favorable to the influence of the sea-water. On the peripheral expansion of the sensory nerves, the cold sea-water makes a fierce impression; the vessels suddenly contract; the heart is slowed; the skin is blanched; the lips are blue, because of the imperfect respiration, and oxygenation of the blood; and the breathing is shallow, catching, and incomplete. The blood retires from the periphery and accumulates in the internal organs, and lowered by the abstraction of heat from its superficial layer, the temperature of the whole mass of blood descends below normal. Presently a change in the condition of the body ensues. In from five to ten minutes, according to the constitutional vigor, the reaction comes on. Then the respiration becomes free, full, and easy, the circulation grows active, the contraction of the superficial vessels is replaced by dilatation, the blanched surface gives way to a warm flush, the blue of the lips is supplanted by a deep carnation, and the coldness yields to warmth, the surface temperature of the body rising. If the bather leaves the water when the reaction is fully established, he experiences a grateful glow—a sense of warmth and well-being—tranquility of mind, drowsiness, and a feeling of contentment and comfort, growing out of the more active performance of the organic functions. Sea-bathing we may well regard as a powerful reconstituent or tonic remedy, when the circumstances are favorable, and no contra-indication exists.

The good results which may be obtained from sea-bathing, are not more conspicuous than the evils which arise from its abuse. The contra-indications are obvious. Those ought not to undertake sea-bathing who are not strong enough to react promptly. If the reaction is slow, the good to be obtained is more than doubtful. If the reaction is imperfect, more or less depression of the vital forces must follow—for the rapid abstraction of heat, the lessened movement of the heart, the jerking and shallow breathing, are not compensated for by the increased heat production, the deeper respirations, and the quickened circulation of the blood which follow the

first period of depression on entering the water. Those who experience ill results from imperfect reaction, suffer from occipital headache, backache, and muscular soreness generally; the appetite becomes poor, the digestion feeble; they sleep poorly if they do not get into a condition of wakefulness, and ultimately grow into an anæmic state with much bodily weakness.

A weak heart from fatty walls or dilatation of the cavities, is a serious contra-indication of sea-bathing. On entering the water, the surface blood, having lost some of its proper heat, is suddenly precipitated on the heart, inducing, it may be, a prompt paralysis of the organ. Atheromatous cerebral vessels are equally dangerous, for when the superficial arteries contract, the intra-cranial blood pressure rises in a corresponding degree. An instance of remarkable lack of judgment on the part of a physician, recently came under our observation, *apropos* of this subject. A gentleman of sixty-five having well-marked atheroma of the vessels, and who had experienced a short time before an attack of thrombosis of a cerebral artery, followed by right hemiplegia, was advised a course of sea-baths at a point on the coast where the temperature of the water is always low! Fortunately the patient had a well-grounded apprehension that some mischief would result, if he carried out the advice given him, and refrained from bathing.

A sea-bath should not be entered soon after a meal, and it is equally injurious after a long fast. The body should not be heated by active exercise, just before entering the water, and a state of bodily fatigue is not less hurtful. Some moderate walking exercise, to call out the energy of the cardiac and respiratory centres, is useful as a preliminary. Only the most vigorous persons, accustomed to the sea, should plunge at once into the water, immersing the whole body. The less vigorous should content themselves with a gradual immersion. Active movements, as far as practicable, should be carried on whilst in the water, and when reaction is fully established the time has come for leaving the bath.

Sudden and unexpected deaths in the water are by no means uncommon. We hear of expert swimmers, in good health, seized with some surprising disability, and sinking unobserved or failing without apparent cause, before rescue can reach them. The condition known as "cramp" may explain some of these instances. When the muscles are kept in vigorous action in such a medium as sea-water, they labor under a tremendous disadvantage. The heat of the body is continually and rapidly abstracted; the superficial portion of the blood cooled, the action of the heart is thereby depressed, and the nervous centres in general perform their functions less energetically in consequence. Sudden paralysis of the muscular system might, under such circumstances, readily occur. Some of those in apparent health, who indulge in sea-bathing, have damaged organs, weak hearts, adherent pericardium, atheromatous vessels, etc., morbid states of the existence of which they may be entirely unconscious. The shock, the depression, and the reaction, awake the unsuspected malady to a sudden activity. Sudden deaths, unaccountable as they appear, are thus explained.

In suitable cases sea-bathing renders an incontestable service. That lowered condition of the vital forces due to sedentary habits and an indoor life, is greatly improved by sea-bathing. In no state is this remedy more conspicuously serviceable than in chronic malarial poisoning with the attendant phenomena. In simple lithæmia sea-bathing promotes oxidation and the elimination of the products of waste. The group of strumous diseases, incipient phthisis, if there is strength enough for vigorous reaction, nervous dyspepsia, simple wakefulness without cerebral lesion, etc., are amongst the maladies in which the best results may be expected from sea-bathing.

CONVALLARIA MAIALIS.

MUCH attention has recently been excited in France over publications made by MM. VULPIAN and SÉE, in regard to the remarkable properties of an alkaloid obtained from *Convallaria maialis*. This is a beautiful annual plant, belonging to the asparaginaceæ, and its common name is "Lily of the Valley." According to Huseman, Valx, so long ago as 1830, isolated two glucosides—*convallamarine* and *convallarine*. In 1865, Stanislas Martin obtained an alkaloid *maïaline*, and an acid, *maïalic acid*, an essential oil, coloring matter, etc. The active principles seem to be maïaline and convallamarine, the other glucoside being inert or nearly so. The extracts of the root and of the leaves have emeto-cathartic properties. The preparation with which the experiments of Prof. G. Sée were made, after many investigations by Hardy, consisted in an aqueous extract of the different parts of the plant, from which the purgative resinous principle was removed. This extract is solid, of a brilliant black color, agreeable odor, very bitter taste, and soluble in all proportions in water and alcohol. The ordinary dose of this extract used in the treatment of cardiac affections is 50 centigrammes (about 8 grains). Hardy has obtained convallamarine in the amorphous state, and, thus prepared, it is a principle comparable in activity to pure digitaline, which it resembles in its mode of action, although there are differences.

Convallaria is readily taken, does not produce nausea, and rather stimulates than depresses the

appetite. The evacuations are somewhat more numerous, although diarrhœa does not occur. On entering the blood, it has an immediate effect on the heart, the vessels, and the respiration. It slows the heart by exciting the cardiac terminations of the vagus, but the irritability of the inhibiting nerve is not lost, for electric excitation of the vagus still arrests the movements of the organ. It increases the blood pressure, whilst it augments the power of the heart. It increases the depth of the inspirations, and improves the sense of respiratory well-being. Its diuretic action is prompt and considerable, and, after it is discontinued, the increased action of the kidneys is maintained for several days. The relative proportion of the urinary constituents is maintained at the normal standard.

Notwithstanding its remarkable action on the heart, convallaria does not disturb the functions of the nervous system in any way.

According to Prof. Sée, the indications for the use of this remedy are—

Palpitations, which are due to depression in the functions of the pneumogastric nerve;

Simple irregularity, with or without lesions of the valves, or orifices, or with or without hypertrophy;

Mitral obstruction, uncompensated, and mitral insufficiency, especially when there is a venous stasis in the lungs and dyspnœa, with or without neuroses of the respiratory organs;

In dilatations, with or without hypertrophy or fatty degeneration, or sclerosis of the muscular tissue;

Finally, in all cardiac affections accompanied by general œdema or dropy. It does not long remain in the system, and hence there is no danger of accumulative action. Prof. Sée regards it superior to digitalis in all of the conditions above mentioned, especially as it does not distress the stomach, and affect the cerebral functions, and does not exhaust the irritability of the inhibiting apparatus.

At the meeting of the Therapeutical Society of Paris, of July 12, some additional facts, supporting the statements of Prof. Sée, were reported by MM. Moutard-Martin and C. Paul, especially the remarkable diuretic property of the remedy in cardiac dropsy was brought out.

MEDICAL ADVERTISING.

APROPOS of the expulsion of a member from a Chicago medical society, for publishing his card in a newspaper and paying for it, the *Times* of that city proceeds to discuss medical advertising from a non-professional standpoint. It calls attention to the fact that no person in the community but a physician has his business, profession, or occupation mentioned on his visiting cards; that no one else expects to have them specified when he is introduced to a stranger; and that, with few exceptions, no one else designates them when he writes his name on a hotel register. It asserts that while the advertising columns of a newspaper are closed to the enterprising practitioner, the society columns are open, and his name, title, and residence can be given in full every time "he goes fishing, visits his mother-in-law, or sprains his ankle." He may also, with ethical propriety, according to the *Times*, write and publish communications on impurities in drinking-water, or on germ theories of disease; he may say how swimming-schools should be conducted, or discuss any other subject presumably of public importance; and he never forgets to sign not only his own name, but the name of his occupation and his place of business.

The *Times* argues, in more serious vein, that in a large city it is very desirable to know the names of physicians in particular vicinities, and the hours which they devote to calling on patients, and that no code of ethics should forbid a person the right to inform an intelligent public in relation to matters it desires to become acquainted with.

Such information is, however, in every large city easily attainable. The general directories and special lists of physicians may be consulted at any drug-store, and are much more complete than the advertising columns of a newspaper are ever likely to be.

Were there no other objections to placing professional and business advertising on the same footing, its tendency would inevitably be degrading, from the fact that, while the merchant or manufacturer may with all propriety and modesty call attention to the excellence of his wares, the professional man in doing so is glorifying himself—never considered a gentlemanly or a praise-worthy employment.

"Where boasting ends, there dignity begins."

As to the term "doctor," its restriction to practitioners of medicine and surgery, and its habitual use by them and by the public, as a distinguishing designation, is, to some extent, an Americanism, and is probably due to the fact that, while in this country, every respectable physician must be a doctor of medicine, the lawyer is not always a doctor of laws, and the clergyman is but rarely a doctor of divinity. Originally, a merely honorary appellation conferred upon certain masters of arts, it was extended first to law, and then to divinity, but it was not until the fourteenth century that, either in England or on the continent, it began to be conferred in medicine. It has not been monopolized by our profession here or elsewhere, nor employed for purposes of display, or gratuitous advertisement, but is simply an involuntary recognition by the pub-

lic of the absorbing nature of the practice of medicine, and of the devotion to it which is so almost universally manifested by its followers.

We may admit, however, that it is just possible that, as to some of its points, the *Times* had a glimmer of reason, and it might be well that medical societies should watch other than the advertising columns of the newspapers.

CHOLERA AND OTHER QUARANTINES.

THE Ottoman Board of Health has constructed a huge lazaretto for the accommodation of six thousand pilgrims, with hospitals, offices, staff of doctors, inspectors, etc., on the island of Kamaran. This island is about 150 miles north of Bab-el-Mandeb. It contains about forty square miles, has an abundance of good water, and is in every way suitable for a quarantine station. The regulations of the *Conseil International de Santé*, published June 20, 1882, require vessels to touch at the island for medical inspection, when, if there is no sickness on board, they are quarantined for five days, during which the pilgrims, their clothes and baggage, and the vessels are submitted to disinfection. But the suspicion of choleraic disease entails a quarantine of observation, lasting from ten to fifteen days, when, if no further developments occur, the pilgrims are permitted to proceed on their journey. With cholera present on the vessel, the hospital service is brought into requisition, and the quarantine prolonged until it is considered safe for the vessel to leave.

An institution of this kind is an obstacle in the westward pathway of cholera from which we, in America, will derive undoubted benefit. Lazarettos and quarantines began in the far East, and from the extent of the recently established station and the character of its rules it is evident that they have profited by experience. At the same time it is obvious that we have no great reason to consider ourselves advanced in matters of this kind, because New York quarantine guards the neighboring ports, or Ship Island acts as a diverticulum to the local quarantines of the Gulf. In progress of time, if our health boards are fostered, we may be able to repel the attacks of exotic disease. Year by year we are gaining experience, but we pay needlessly high for it. Next year Texas will probably organize a State Board, or make some arrangement to guard the line of the Rio Grande.

PETROLEUM IN DIPHTHERIA.

DR. LAMARRE, of Saint-Germain, has lately employed petroleum oil topically, with very encouraging results in an epidemic of diphtheria. Archambault has tried it in the Children's Hospital, but without any obvious advantage. In two severe cases it was used, with the result that one died and the other recovered. In the case which recovered there were albuminuria, engorgement of the cervical glands, and nasal diphtheria. Petroleum is a rapid solvent of the false membrane, and must possess distinct advantages under some circumstances. This fact, coupled with its antiseptic property, renders it a promising remedy, although its odor always renders its use disagreeable. It has accomplished sufficient results to justify its further use. We believe that it has been applied more or less in this country, but we are not aware of any published results of the treatment.

FIRE ESCAPES AGAIN.

SOME time since we called attention to the need of fire escapes for hospitals as well as other public buildings. We have just learned of a plan which seems to us so remarkably good that we call attention to it in the earnest hope that it may be widely adopted. In the Ontario Mill, now building by Mr. William Arrott, in Kensington, a tower is placed at each end of the building, and is used as the only means of access to the mill. No doorways or other openings exist between the mill and the towers, but all ingress and egress are by outside iron platforms passing around from the towers to the mill. These may be in the rear and so not be an unsightly feature.

The towers are capable of excellent architectural treatment, so as to add to the appearance of the mill instead of detracting from it; the operatives are accustomed to it by daily use, and have no new experiment to try when bewildered by fire, and it would seem to be entirely safe. It combines, so far as we see, all the advantages and none of the disadvantages of other plans, except that of being perhaps a little more costly than some of them.

For hospitals this would appear to be peculiarly adapted, both hygienically and architecturally.

THE TREATMENT OF ACUTE STHENIC PLEURISY.

DR. GUYON has recently tried the various plans of treating pleurisy on an extended scale, and his results are embodied in the following propositions:

Acute sthenic pleurisy must be treated energetically at the onset of the disease, as the expectant plan is dangerous.

The Arabic method, which consists in withholding all fluids, and using alterants to promote absorption, gives bad results.

Diuretics, purgatives, and sudorifics are uncertain measures, and do not in themselves constitute a method of treatment.

Applied at the beginning of the malady, wet cups suppress the pain, diminish the dyspnœa, and apparently arrest the progress of the exudation, and are

to be preferred to blisters, which are, indeed, contraindicated at this period of the disease.

When a marked degree of gastro-intestinal catarrh exists, emetics and cathartics are usefully added to other antiphlogistic measures.

The duration of an acute pleurisy treated by mercurials is relatively long, and the patient is exposed to unpleasant accidents.

During the febrile state thoracentesis should not be practised unless the effusion is so great as to endanger life.

If the medical treatment has been without result, it is well to puncture after the fever has ceased, and not depend on absorption, whether it be expected to take place spontaneously or under the influence of revulsives.

In view of the above, may we not inquire if it has been wise to abandon venesection altogether in cases of acute sthenic pleurisy? Have not effusions, serous and purulent, been more frequent and extensive since venesection has not been employed?

REVIEWS.

Mittheilungen ueber Fragen der Wissenschaftlichen Medicin. Von Wilhelm Koch in Dorpat. Heft I., Beiträge zur Lehre von der Spina Bifida. Papers on Questions in Scientific Medicine. Part I., Spina Bifida. 4to. pp. 62, pl. 5. Theodor Fischer Kassel, 1881.

The author enters very exhaustively into his subject both as to the pathology and the literature of the subject. The only wonder is that he did not also give a complete bibliography of the subject, which would have rounded it out. The style is obscure and difficult. Indeed, we have not run across so many obstacles in German for a long time as in this book. It is in five parts, treating respectively of myelocele or hernia of the cord, and dropsy of the subarachnoid space; congenital fissure of the vertebral arch, rachischisis posterior; anterior fissure of the vertebræ, rachischisis anterior; meningocele; and finally the treatment of those forms amenable to art, viz., myelocele, meningocele, and certain limited forms of fissure. He condemns the usual mode of reporting every form of such allied disorders under the generic name of "Spina Bifida," and especially in relation to treatment. Tables such as Wernitz's, in which no proper distinctions are made, are, therefore, practically worthless. Evidently he has little faith in Brainard's method of iodine injections, or of Morton's modification of it, and prefers, according to the case, plastic operations, exsection of a piece of skin, subcutaneous ligature of the neck of the sac, etc. For details the reader must wrestle with the original.

The New Hand-book of Dosimetric Therapeutics, or the Treatment of Diseases by Simple Remedies. By Dr. Ad. Burggrave. *Translated by* Henry Arthur Allbutt, M.R.C.P.E., etc. Pp. 208. With a Frontispiece—a portrait of Dr. Burggrave. London: David Bogue & Co.

We are asked to believe that the Dosimetric System is a new method. In the confines of 208 pages, Dr. Burggrave unfolds the mysteries of his "system," but when we have patiently examined the data given by him we find nothing new but terms. Instead of crude drugs, small and often repeated doses of active principles are used, but in their applications we discover no new facts or methods. If the book were put forward as an appeal for a more rational method of administering our remedies, the motive for its appearance would be ample. But under the present auspices, and supported by the high pretensions of its advocates, dosimetric medicine has a quackish appearance. The irregularity is still further apparent in the way in which the medicines are to be obtained. "No granules are genuine or reliable, but those manufactured by M. Charles Chauteaud, the eminent Parisian pharmacist," says Dr. Allbutt in his preface.

Whilst we have only commendation for all enlightened efforts to improve the administration of drugs, we must express our strong disapproval of the groundless pretension and false teaching of this work. Dosimetric, we doubt not, is an effort to offset homœopathic, and to curry favor by scientific pretensions which have no real foundation.

Colles's Fracture. By J. F. Knott, L. K. and Q. C. P. I., etc. A paper read before the Surgical Society of Ireland, January 12, 1881, and reprinted from *The Medical Press and Circular*. 8vo. pp. 25. Dublin: John Falconer, 1882.

The first thing that strikes us in examining this essay is the fact that the title is spelt right, and leaves no excuse for the careless but common mistake of calling this "Colley's" fracture. The next is the use of the inexact expression "from above and behind downwards and forwards," in describing the line of fracture. In speaking of the radius, this might be understood to be with the hand in extreme supination; but it would be better if authors used the unmistakable terms "palmar" or "dorsal aspect," especially as we observe that this one once uses the word "anterior" when the arm must be in pronation and the dorsal aspect of the radius in front.

Next we come upon a reference to the "*arch*" of a segment of a circle and its "*cord*." After which we enter a zone of French terms: "*coup d'œil*" and "*mouvement de la bascule*," with "lezarde or baillement of architectural ornamentation," and "*coup de hache*," fractures "*par écrasement, penetration* (no accents), and *arrachement*," together with deformities "*en Z*." Does the author not know how to put these into good English? or does he fancy the whole medical public has the same easy and familiar acquaintance with the French language which he appears to have? If not, is it to prevent the ignorant from feeling too much shamed that he prints "*abduction de totalite, en etoile*," etc., without accents, and over and over again, "*médicine*" for *médecine?*

So much for the manner of the author. His matter is quite different, and of such excellence that we regret to find it burdened with the lapses from good literary style to which we have alluded.

The substance of the paper is an account of the various views that have been held as to the nature and mechanism of fractures near the lower end of the radius. The author quotes Continental and American opinions, in addition to those of British writers, and concludes his review of the subject with this sensible observation: "An examination of all the facts and theories which we have collected on this subject will, we think, leave no doubt on (*sic*) the mind of any unprejudiced inquirer that a great variety exists in the form, and probably, also, in the mechanism of pro-

duction, of the fractures of the lower end of the radius. . . . I have not myself come forward as an advocate of any one hypothesis, for I do not believe that any one can be manipulated so as to adapt it to all cases; nor do I attempt to teach any new theory; for I think there is no room left for further innovation, and those with which we are already acquainted, if judiciously applied, will be found amply sufficient."

We would have enjoyed it more if a less meritorious paper had given us the opportunity to speak our mind freely against the use of foreign words when there are plenty of English ones just as good. At the same time we are glad to be able to make some amends for our criticism of the author by acknowledging the genuine worth of what he has written, and commending its perusal to the many young men now engaged in writing works on surgery.

CORRESPONDENCE.

LETTER FROM BRUGES.

Bruges, Memling, and the Hospital of St. John.

BRUGES is the Pisa of Flanders. It has receded from the sea, so to speak, and, like a stranded vessel, is being slowly consumed by the gnawing tooth of time. Its docks, where vessels once discharged curious cargoes from every foreign port, are dried up and covered in with houses; its various canals are choked with seaweeds; its once thronged streets, paved to last for ages with blocks as solid as those of Pompeii, now re-echo the rumble of the solitary vehicle, and the great open squares, upon which assembled the citizens of an opulent metropolis in rejoicing, in commiseration, or in vindication of their rights, are all deserted save by the peasantry in their quaint garbs, or the occasional traveller who hurriedly takes in Bruges on the way from Ostend to Brussels. One may thoroughly feel, but find it hard to describe the sense of desertion, the air of melancholy which pervades the place.

But the lovers of art must always pay a visit to Bruges to look upon the mediæval architecture of Flanders, which distinguishes this city more than any other in all the low countries, and more especially to study the history of painting in the works of the earliest masters of that art. Outside of the museums the old European traveller naturally looks for many of these wonderful works in the churches, and even the unbeliever must be grateful to the church, not only for the source of their inspiration both in matters of faith and finance, but also for their careful preservation through ages of vandalism and image destruction. But here in Bruges some of the very finest specimens are to be found in an entirely unexpected place, namely in the hospital. The story goes—pity that it is not true—that Memling was carried wounded to the hospital, and that he left all these marvellous works in gratitude for his restoration. But however they got there, here they are still as fresh as when they left the master's hands some four hundred and fifty years ago, and a handsome revenue they must make in the course of the year to the resources of an institution which really does not need it, as it is already so richly endowed.

One must speak of the pictures in attempting to describe the old hospital of Bruges, as it is impossible to get a proper idea of it, except from some of the pictures which portray it as it was half a thousand years ago. For the old hospital has been long since abandoned for a new one built next to it upon the grounds, somewhat, though not much, more modern in its style, a quadrangular structure containing twenty-four wards, with room for about six hundred sick, enclosing an open court which is pleasingly laid out in garden form.

How far back into time the history of the old hospital goes, nobody here seems to know. But here it stands now, on the outside at least, just as it was in Memling's time—a great irregular mass of buildings, like a venerable abbey, with turrets and towers, niches and shrines, crumbling, moss-grown, gray with age, but still in such preservation as to be good for a century or so to come. On the inside it looks like one of the old mediæval churches, enough like it to have been one in its day, with pillars and arches and pavements all of solid stone. Twenty feet from the floor the windows begin, and then run up arching at the top to the ceiling, with little panes of green glass like those in an old Gothic church. The beds, as is seen in one of the old pictures in the chapel or room in which the whole collection is shown, were arranged like the bunks in the steerage of a ship, in two rows, one above the other (the upper being arrived at by ladders), between the short pillars which support the heavy arches along the middle of the hall, and in two additional rows along the side walls. A more unwholesome, subterranean-like arrangement could not have been devised. But here it was that Memling, the great artist, was sick; for here he is shown in another picture engaged at his work, and being visited in state by Mary of Burgundy, with her maids of honor, who are in turn being regarded with admiration by the good sisters and brothers in charge of the house. These pictures are not regarded as works of any artistic merit, and are spoken of very slightly by the usher who can not understand the construction of a visitor who dwells upon them with many pertinent, which he evidently regards impertinent, questions; but these old pictures stowed away in a bad light are of far more interest to the medical historians than the shrine of Ursula and the slaughter by the brutal soldiery of the eleven thousand *virgines intactæ*, which it so graphically portrays. For these two old pictures complete the history of the old hospital, and it is fortunate that they still exist, for nobody about Bruges knows anything about the old hospital more than is contained in these few lines. The doctors here looked upon your correspondent rather as a kind of morbid specimen for evincing any curiosity about the old hospital building, and they could give no reference to any possible source of information. When I saw the iron rings in the operating-room for the reduction of dislocations still in use, and curtains everywhere drawn close about the beds in the present hospital wards, I was not surprised at the general Rip Van Winkle air which surrounds the place. At the library I had equal bad luck. There was a solitary antiquarian rummaging about the ancient literature, and he informed me that he did not think I could find anything concerning the hospital, unless among the musty archives of the church. This much, however, I did glean at last; that when the *sans culottes* of the French revolution came over and turned everything upside down, they took the hospital away from the church, and ever since that time it has been in the hands of the city government, which now appoints the hospital staff. But there is need of another revolution, a *bouleversement* as complete as the first, to bring the hospital at Bruges up to the standard of modern times.

J. T. W.

BRUGES, August 22, 1882.

VIRULENCE OF HUMAN SALIVA.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: I am glad to learn from Dr. Formad's letter of August 1st (MEDICAL NEWS of August 12th), that the reporter, and not my esteemed friend, is responsible for the "inacurate statement" which I found it necessary to correct, in the interest of truth. Of

course, I have no fault to find with Dr. Formad for drawing his own conclusions from the experimental data which I have published, but I can not help thinking that his memory is at fault with reference to the facts recorded, and especially with reference to my own deductions from these facts.

I trust, however, that yourself and your readers will not imagine that in addressing you a second communication upon this subject, I am actuated by a controversial spirit, and propose to occupy your valuable space in an effort to prove the infallibility of the writer. This would, indeed, be a difficult and unprofitable task, as I do not myself accept any such dogma. But I do believe in the logic of facts, and, although well-attested facts often appear to contradict each other, I believe that such contradiction is only a superficial one, and that it may always be reconciled by a fuller knowledge, as *there are no contradictions in nature*.

The case of Dr. Formad's "buck-rabbit," which is "to-day perfectly well and happy" after having been subjected to a long series of experimental inoculations, is a case in point, and I think it may be made profitable to your readers by using it to call attention to the subject of protective inoculations, a subject of great interest to physicians and one which deserves to be fully studied by the experimental method.

But first permit me to answer briefly the points made by Dr. Formad in the following quotation from his letter:

"Dr. Sternberg was the first, etc. . . . . But his experiments are not extended enough to prove his conclusion that the lethal effects are due to a poison *peculiar* to the saliva; and, moreover, by no means warrant his deduction that only certain saliva has poisonous effects, and that some saliva lacks such properties, viz., does not kill rabbits."

I answer (*a*) that I have never claimed that the lethal effects of human saliva, upon rabbits, are due to a poison "peculiar to the saliva;" and (*b*) that my recorded experiments and the experiments detailed by Dr. Formad in his letter—case of the buck-rabbit—show conclusively that all human saliva is not fatal to rabbits. In my first report to the National Board of Health (*Bulletin*, April 3, 1881), I say injections of a small quantity of surface-mud from the gutters of New Orleans invariably produced fatal results within forty-eight hours.

In the report referred to I presented in detail the experimental evidence which led me to the conclusion that the virulence of human saliva is due to the presence of a micrococcus constantly found in the fluid. This conclusion is sustained by subsequent experiments made by myself and by the experiments of Dr. Claxton.

This deduction rests upon experimental evidence of the same kind as that upon which anthrax is proved to be due to a bacillus, fowl-cholera to a micrococcus (Pasteur), and septicæmia in the mouse to a minute bacillus (Koch). But I have not claimed and do not believe that the micrococcus found in human saliva, and to which it owes its virulence, is *peculiar* to this fluid. On the contrary, I believe it to be widely distributed in nature, and think it not improbable that it may be found in the saliva of animals. I should therefore be greatly indebted to Dr. Formad if he will publish in detail the experimental data which induce him to formulate the generalization that "*any and all saliva kills certain rabbits*." Certainly a very extended series of experiments is required to sustain this generalization. I am particularly anxious to know whether the saliva of herbivorous animals has been found as virulent as that of the carnivora; whether the saliva of monkeys is as virulent as that of man, etc.

I am not prepared to accept Dr. Formad's explanation, which ascribes the marked difference in the results of experimental inoculations to a difference in susceptibility of the animal experimented upon, rather than to a difference in the fluid injected. For I have ascertained by repeated experiments, made at different times and places, that my saliva kills rabbits infallibly within forty-eight hours, with certain exceptions which I have noted in my report of experiments with disinfectants.[1]

I quote from the last-mentioned paper: "I can no longer say *infallibly* produces death, as in several instances death has not occurred *in rabbits previously injected with saliva mixed with certain substances*—alcohol, quinia—*which when added to it in a certain proportion prevent the fatal results*, but do not prevent an impression being made by the mixed injection, which seems subsequently to protect the animal from the lethal effects of injections of saliva alone."

The following experiment is quoted from my report first mentioned in illustration of this statement:

"*May 24, 1881.*—Injected into a large rabbit (*the subject of a previous experiment*, May 13, in which a negative result was noted, and in which 0.5 c.c. of virus treated with 1 per cent. solution of sodium hyposulphite was injected) 1.25 c.c. of virus, not disinfected, from a rabbit recently dead. Result negative."

This virus—bloody serum from a septicæmic rabbit just dead—was proved by other experiments to be fatal to *unprotected* rabbits in the smallest quantity, but this animal suffered no harm from so large an amount as 1.25 c.c. Is it probable that the remarkable immunity shown by this animal, and by the buck-rabbit referred to by Dr. Formad in his letter, is due to an accidental idiosyncrasy, and that the previous injections had no importance. Dr. Formad records that his rabbit "*had been largely dosed by his friend Claxton, with saliva of some kind.*"

I would remark as follows upon the record given of this case:

"1. Human saliva (second time)." The first inoculation, or the previous inoculations by Dr. Claxton, accounts for the protection which this animal enjoyed from subsequent inoculations, and the fact that the animal did not die after the first injection of human saliva, is evidence in support of my statement that all human saliva does not kill rabbits.

"2. Cancer-juice." Numerous experiments made in Dr. Formad's laboratory, show that cancer-juice is innocuous. Dr. Wile reports as the result of twelve experiments, that "the animals were kept under observation for one year, and careful autopsies revealed no trace or effect of the injected juices.[2]

"3. Epidemic diphtheritic material from Michigan." Numerous observers have recorded the presence of micrococci in material of this kind, which appear to be morphologically identical with those found in the normal buccal secretions. May not this be a pathogenic variety of the common form, which has the power of penetrating mucous membranes, and giving rise to fibrinous exudation, and necrosis of invaded tissues, instead of remaining in the buccal cavity as a harmless parasite, nourished by the salivary secretions, and shed epithelium constantly present in this locality? If this is the case, we can understand how the previous injections of normal saliva protected this animal from suffering any ill-effects from this, and subsequent injections of diphtheritic material.

We have abundant experimental evidence that protective inoculations may be practised in various forms

[1] Nat. Board of Health Bulletin, July 23, 1881, p. 22, and in a paper published in the Am. Journal of the Medical Sciences, July, 1882, p. 73.

[2] Phil. Med. Times, Aug. 12, 1882, p. 771.

of septicæmia, *e. g.*, anthrax, fowl-cholera, swine plague;[1] and an "attenuated virus" (Pasteur) may be obtained by various methods, *e. g.*, method of Pasteur by long exposure to oxygen, method of Toussaint by short exposure to a temperature of 52° Cent.[2]

My own experiments indicate that in the form of septicæmia in the rabbit, which I have specially studied, various chemical agents, which in a certain proportion completely destroy the potency of the septic virus, may in a certain less proportion modify its virulence, and that thus an "attenuated virus" may also be produced, the introduction of which beneath the skin of the rabbit results in protection from the effects of lethal doses of unmodified virus.

But it is not necessary that artificial inoculation with "attenuated virus" should be practised in order that a rabbit may enjoy protection from infectious septicæmia. Accidental inoculation may occur, or the rabbit may suffer a non-fatal attack as the result of contact with other septicæmic animals, or from being placed in infected cages. Davaine[3] long since recorded the fact that spontaneous septicæmia occurred among his rabbits from this cause, and I have myself lost a number of rabbits in the same way,[4] while others of the same lot recovered after a brief illness, and subsequently proved to be protected from the lethal action of septic virus.

Finally, I would say that my conclusions have not been drawn from a small number of experiments, and that I have carefully compared the results obtained by myself from human saliva, *my own*, with those reported by Braidwood and Vacher, in which lochial fluid undergoing putrefaction and other septic material were injected into rabbits.[5] My experiments with disinfectants, alone, cost the lives of more than forty rabbits, and careful post-mortem examinations in nearly all of them fully confirmed the observations previously detailed in my first report (a fatal form of septicæmia, etc., *l. c.*) as to the presence of the micrococcus, the diffuse cellulitis extending from the point of inoculation, etc.

I have not yet found time to follow up the investigation relating to protective inoculations; but, as this is a question of great importance from a practical point of view, I take the liberty of making two or three suggestions for the benefit of those who may have better facilities for pursuing experimental work than I enjoy at present.

Will the introduction into the body of a susceptible animal of the chemical products evolved during the growth of septic organisms—Anthrax bacillus, bacillus of Koch's septicæmia in the mouse, micrococcus of fowl-cholera, micrococcus of induced septicæmia in the rabbit—furnish protection as well as a living "attenuated" virus?

Will an attenuated virus of any of these forms of septicæmia furnish protection against others in the list?

Will the hypodermic or internal administration of any of the known germicides cure an animal which has been inoculated with a lethal dose of a septic virus? and if so, in what quantity must such agent be used to produce the desired effect?

Yours, very truly,

GEORGE M. STERNBERG, M.D.,
Surgeon U. S. A.

A SPLINT TO REPLACE THE STROMEYER.

To the Editor of THE MEDICAL NEWS.

SIR: In your issue of August 26, I noticed under the head of *New Inventions*, a description of "a new splint to replace the Stromeyer," by Dr. W. W. Keen, of this city.

Six months ago I had a patient suffering from anchylosis of the elbow-joint, for the relief of which she had been using Stromeyer's splint. Although able to extend the arm with it, I found upon flexing that the splint produced so much excoriation of the skin and pain from pressure on the nerves and bloodvessels at the joint, that it was abandoned as useless.

I had a splint constructed that not only enabled me to flex the arm fully (a feature lacked by Stromeyer's), but remedied the trouble referred to. Instead of a hinge the boards are connected on either side by two pieces of iron riveted together, leaving a space of three inches between the two splints, thus relieving the joint of any pressure. To the arm-piece is secured an iron plate with a brass head, split and drilled through at right angles. To a plate on the forearm splint is connected a long eight-sided brass nut, held in place by a movable collar that enables the nut to accomodate itself to any angle. The screw, secured above by a pin, passes through the nut, and the latter by turning to the right or left, gives either flexion or extension, as may be desired.

Respectfully yours,

A. H. DE YOUNG, M.D.

PHILADELPHIA, 242 N. FIFTH ST.,
September 5, 1882.

NEWS ITEMS.

PUBLIC HEALTH NOTES.—THE YELLOW FEVER EPIDEMIC at *Brownsville* continues unabated. During the past week the bulletins have announced fifty or more new cases daily, with only two or three deaths. The small mortality is unprecedental in the history of yellow fever. As the population only amounts to about 5000, the disease must soon begin to die out for want of material. The non-intercourse quarantine and guard to prevent the escape of refugees from the infected district has succeeded in confining the disease, but those who have been cooped up to await the expected attack must have felt that these sanitary arrangements are somewhat one-sided. Many, no doubt, have camped out for safety in the adjoining country, as did the people of Memphis in 1879. The garrison of Fort Brown moved several miles up the Rio Grande and have escaped visitation. An early flight from the infected locality, termed by the sanitarians "depopulation," appears to be a good thing for those who are left, as well as for those who get away: the number remaining to be sick and cared for is reduced. The United States soldiers and marines at Pensacola embarked for Mt. Vernon Barracks, Alabama, on the day after the presence of the fever was officially promulgated. The navy-yard quarantined against the city, and late advices from Surgeon A. M. Owens, United States Navy, shows the quarantine to be effective.

The spark which smouldered in *Pensacola* from on or before the 28th ultimo, giving only one or two new cases daily, flamed up suddenly on the 7th inst., when ten cases were reported. This was followed by twelve on the 8th, and sixteen next day, when the city authorities proclaimed the disease epidemic. From the onset to the 11th inst. there have been recorded ninety-two cases and seventeen deaths. A heavy gale and rain storm prevailed on the 9th inst., but did not seem to have any special influence on the progress of the disease.

The City Board of Health continues its efforts to control the spread of the fever by disinfection and isolation. Application was made to the National Board of Health for coöperation and assistance, and estimates for services and supplies were made and forwarded to Washington on the 7th instant, but mail disinfection in Alabama delayed their arrival. We understand that they reached Washington this morning (12th instant), but we have not learned their contents.

The following weekly summary of the progress of yellow fever is furnished by the Surgeon-General of the Marine-Hospital Service, compiled from official reports for the week ending September 9, 1882:

BROWNSVILLE, TEXAS.

Dates.	Cases.	Deaths.
September 3d and 4th,	148	10
" 5th,	67	1
" 6th,	49	2
" 7th,	48	2
" 8th,	57	4
" 9th,	57	3
	426	22
Previously reported,	1,113	66
Total during epidemic,	1,539	88

The number of deaths at Brownsville on the 7th instant was stated in the daily report for that date at ten. The number was two. The incorrect figures were the result of a telegraphic error.

The protective cordon on the Arroyo and river has been effectual up to the present time, and the outer cordon will be dissolved in a few days, as ample time has been given for the appearance of fever between the lines. The ranches will each be inspected from the outer to the inner cordon by the quarantine guards. Authority is awaited from the Governor for the beginning of this work. The Arroyo cordon will be strengthened during the week and persons allowed to pass after ten days' detention and fumigation of clothing. An inspection station has been established at Santa Maria.

PENSACOLA, FLORIDA.

Dates.	Cases.	Deaths.
September 3d,	0	0
" 4th,	1	2
" 5th,	1	0
" 6th,	0	1
" 7th,	9	0
" 8th,	12	2
" 9th,	16	3
Total for week,	39	8
Previous cases uncertain,	0	5
Totals,	39	13

No measures have been instituted in Florida by the Treasury Department for the suppression of the disease, as it was only on Saturday that yellow fever was declared epidemic by the Pensacola Board of Health, and no request has been made for aid.

CHOLERA.—There are rumors at present of the occurrence of cholera in several of the large European cities, but they are probably based upon sporadic cases of virulent character simulating Asiatic cholera, such as have recently been reported in this country in Michigan and at Newport, R. I. The only specific advices which affect us in the United States, are from Yokohama, Japan, where the disease has been existing in an aggravated form since April 28th of this year. For the two weeks ending August 10th, there were 616 new cases and 345 deaths, making, since the commencement of the epidemic, a total of 2193 cases and 1362 deaths. A few cases have occurred among British sailors who have had liberty on shore, but with this exception the disease is confined to the native population. At Tokio and Osaka, the epidemic is equally virulent. Hitherto cholera has reached us from Europe, but the possibility of an attack on the other flank should be borne in mind by our California brethren.

THE ADDRESS OF PROF. GEORGE F. BARKER, of the University of Pennsylvania, on "The Question of Life," delivered before the American Association for the Advancement of the Sciences, has been translated into French, and published in the *Revue Scientifique*, for August 19, 1882.

GALEN'S WORKS.—An important literary and scientific discovery is announced from Salonica. The works of the celebrated physician, Galen, which were supposed to have been lost, have been discovered by M. Papageorges. They are in manuscript; date from the fifteenth century, and appear to have originally formed 248 sheets; 144 are in good condition, 24 are mutilated or worm-eaten, and 80 are missing.—*Brit. Med. Journ.*, August 19, 1882.

PERSONAL.—PROF. GERHARDT has been called to Heidelberg to fill the chair left vacant by the death of Prof. Friedreich.

PROF. ROSSBACH has been called to Jena in Nothnagel's place.

PROF. V. BERGMANN has received the title of Privy Medical Councillor, and PROF. BARDELEBEN the title of Supreme Privy Medical Councillor.

IMMIGRANT-INSPECTION SERVICE OF THE NATIONAL BOARD OF HEALTH.—DR. J. H. RAUCH, Supervising Inspector, presents the following report of the operations in the western district during the month of August:

An aggregate of 16,014 inspections were made by the seven assistant inspectors, who performed 3,125 vaccinations upon immigrants found to be either imperfectly or not at all protected by previous vaccination or attack of smallpox. This is in the ratio of about twenty per cent. of vaccinations, as against sixteen per cent. during the months of June and July.

It is not to be inferred from this, however, that the proportion of unprotected immigrants was larger than in the previous months. On the contrary, increasing evidence has been found, throughout the month, of greater care and vigilance on the part of steamship surgeons generally, and of some of the inspectors east of this district—notably at Port Huron, Michigan—and a much larger proportion of recent vaccinations has been met with as the result of this care and vigilance.

An analysis of the inspectors' reports shows the highest ratio (nearly thirty-eight per cent.) of vaccinations to inspections to have been made among immigrants arriving *via* Baltimore. And this is due to the cause indicated in the last report, namely, the neglect of surgeons of steamers arriving at that port to enforce vaccination, although there has been a very decided improvement in this respect during the past month, as will be seen in the comments of inspectors quoted below.

The smallest ratio of vaccinations to inspections—in other words, the smallest number of unprotected immigrants out of a given number arriving in this district—is that among passengers by the Grand Trunk Railway. Only three and a half per cent. of these were found to need vaccination by the Illinois inspector, that work having been thoroughly performed by the inspectors at Port Huron. The ratio on this road has steadily declined from 36 per cent. in June to 8.3 per cent. in July and 3.5 per cent. in August. During the latter

part of the month *all* of the arrivals by this road were found to be protected.

Of the arrivals in this district during the past three months, observations go to show that 54 out of every 100 immigrants were protected against smallpox before landing in this country, in one of the three following methods; 3 out of every 100 by previous attack of smallpox; 43 out of every 100 by a mature successfnl vaccination; 8 out of every 100 by a recent successful vaccination or revaccination performed on shipboard.

Taking the whole season throughout, only 22 out of every 100 steerage passengers have been vaccinated on shipboard, but this number is nearly doubled for the latter part of August, when it rose to 41 in every 100. Of the vaccinations by the steamship surgeons, 36.7 per cent. are now successful, but there are still nearly two-thirds failures in the aggregate.

Less than 4 per cent. of the arrivals in Chicago are found to have been vaccinated at all eastern points, exclusive of Port Huron; at this latter station nearly 36 per cent. of those destined for Illinois and westward are vaccinated.

In the western district, thus far, a little over 96 per cent. of the unprotected arrivals have been vaccinated by the inspectors within the district, before entering or crossing the State—the 3 or 4 per cent. escaping vaccination being composed of cases where contra-indicating conditions existed, or where the operation was refused.

The necessity for this mode of excluding imported smallpox contagion has received signal confirmation during the month by two local outbreaks of the disease in Illinois, which show that, notwithstanding all the efforts made to secure the proper vaccinal protection of the State, there are still localities where the introduction of the infection is sufficient to discover unprotected individuals enough to cause considerable alarm.

In Jersey County 8 cases and 1 death, up to date of last report, had resulted from a suit of second-hand clothes bought in St. Louis, by a railroad hand, and brought to Elsah, where the first cases appeared in a family to which the clothes were taken to be washed. From Elsah it was carried to Jerseyville, where 3 cases have resulted among hands employed by the Wabash Railroad Co.

Ten cases have occurred near Harrisonville, Monroe County, the source of contagion being infected bedding, clothing, etc., thrown into the Mississippi River, and lodging upon an island, where the outbreak occurred.

With the above exceptions, there has been only one case of varioloid in the State (outside of Chicago) since June 23. The case referred to is that of a farmer returning to Paxton, Ford County, from France, with a cargo of imported horses. He was carried on a Danish stock boat, the *Friga*, and contracted the disease from a stock-man on board, who was suffering with a mild case of varioloid. The attending physician writes that "there was no examination in New York," and as the man did not travel as an immigrant, he, of course, escaped inspection by the service.

In Chicago there have been only 24 cases and 5 deaths during the month, and at the close of the month there were only 3 cases under treatment in hospital, and 2 in the city.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending September 2, 1882, indicate that rheumatism, typho-malarial fever, tonsillitis, and bronchitis have increased, that dysentery has considerably decreased, and that inflammation of the bowels and cholera infantum have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending September 2, and since, at 11 places, scarlet fever at 6 places, measles at 3 places, and small-pox at 2 places, as follows: at Grand Rapids (one case, convalescent); August 28, in Sebewa Township, Ionia County (convalescents), August 30.

August 27, a case of cholera, resembling Asiatic cholera, was reported to have occurred in Adams Township, Hillsdale County. No other case has been reported.

THE ENGLISH DEATH RATE.—From the weekly return of births and deaths in London, and twenty-seven other large English towns, for the week ending August 19, we learn that the annual rate of mortality averaged 23.8 per 1000 of their aggregate population, which is estimated at 8,469,571 persons. The rates of mortality in the several towns ranged from 16.3 in Birkenhead to 33.4 in Nottingham, that of London being 20.5. The deaths in London during the week numbered 1528, and these included 5 from small-pox, 41 from measles, 40 from scarlet fever, 17 from diphtheria, 52 from whooping-cough, 11 from enteric fever, 1 from an ill-defined form of continued fever, 164 from diarrhœa and dysentery, 11 from simple cholera, and not one from typhus fever. Eighteen new cases of small-pox were admitted into the hospitals during the week. Small-pox also caused one death in Wolverhampton, one in Nottingham, one in Newcastle-on-Tyne, and three in Birmingham.

During the same week the death rate in eight principal towns in Scotland was 20.7 per 1000 of the estimated population; Perth giving the lowest rate, 17.2, and Paisley the highest, 32.1.

OBITUARY.—Died at Trieste on Saturday, September 9th, BENJAMIN F. GIBBS, M.D., Surgeon U. S. Navy. Dr. Gibbs was Medical Inspector on board the United States Steamer Lancaster, and had been ill some time when Trieste was reached. His death took place at the hospital, whither he was conveyed. Surgeon Gibbs was a native of New Jersey, from which State he was appointed Assistant Surgeon in 1858. His commission as Medical Inspector dated from March 17, 1876.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 4 TO SEPTEMBER 11, 1882.

HUBBARD, VAN BUREN, *Major and Surgeon.*—Orders to Fort Wingate, New Mexico, revoked. To report to Commanding Officer District of New Mexico for duty at Fort Stanton, New Mexico.—*S. O. 174, Headquarters Department of the Missouri, August 30, 1882.*

COMEGYS, E. T., *Captain and Assistant Surgeon.*—Assigned to duty at Fort Supply, Indian Territory.—*S. O. 174, Department of Missouri, August 50, 1882.*

CORSON, JOSEPH K., *Captain and Assistant Surgeon.*—Granted two months' leave of absence.—*S. O. 210, A. G. O., September 9, 1882.*

SHUFELDT, ROBERT W., *Captain and Assistant Surgeon.*—Now awaiting orders, to report by letter to the Commanding General Department of the South for assignment to duty.—*S. O. 209, A. G. O., September 8, 1882.*

TAYLOR, MORSE K., *Assistant Surgeon.*—Relieved from duty as Attending Surgeon at Detroit, Michigan.—*S. O. 157, Department of the East, September 9, 1882.*

WAKEMAN, WILLIAM J., *Assistant Surgeon.*—Assigned to duty at Fort Douglas, Utah.—*S. O. 91, Department of the Platte, September 1, 1882.*

ORIGINAL ARTICLES.

THE THORACOPLASTIC OPERATION OF ESTLANDER:

MULTIPLE AND EXTENSIVE RESECTION OF THE RIBS OVER OLD AND INTRACTABLE EMPYEMA CAVITIES, AS A MEANS TO EFFECT THEIR CLOSURE.

BY CHRISTIAN FENGER, M.D.,
OF CHICAGO, ILL.

IN the last twenty years the treatment of empyema has gradually drifted from the repeated aspirations, through the stage of the use of the permanent canula, into the stage of free incision, with excision of a piece of a rib, if necessary, and with thorough drainage, with or without the washing out of the cavity.

The repeated aspiration will possibly retain a permanent place in the treatment of empyemas in children: the permanent canula will never attain its object, namely, to shut out air from the pleural cavity, except when evacuation and washing out is performed. It will, consequently, have to be abandoned in favor of the more effective method of free incision. But it was natural that the two first-named methods should have their trial before the advent of antiseptic surgery, which has enabled us to so disinfect the air entering the pleural cavity through the drainage tube at each inspiration, as to render this air free from noxious germs, and, consequently, harmless.

The antiseptic method, then, is a *conditio sine qua non* for the employment of the method of free incision; it also enables us to treat the cavity on rational modern surgical principles; that is, to have two openings—an anterior and a posterior, and sufficient drainage through these to effect not only the evacuation, but also the thorough washing out, and, if necessary, the disinfection of the cavity.

Dr. A. Homén, in his interesting paper on Estlander's method (Langenbeck's *Archiv für klinische Chirurgie*, Band xxvi., Heft 1., page 151, 1881), has been able to gather statistics of fifty-two cases of empyema treated by free incision, with all antiseptic precautions. Of these, fifty per cent. recovered, thirty-three per cent. died, and in seventeen per cent. permanent fistulæ remained.

Homén's total statistics include one hundred and forty-one cases treated by free incision, but in all of which strict antiseptic precautions had not been observed. As may be expected, the results of the operation are less favorable than in the class of cases just mentioned. Of these, forty-six per cent. recovered, thirty-three per cent. died, and a permanent fistula remained in twenty-one per cent.

As our attention is to be called only to the treatment of permanent pleural fistulæ, we will now look a little closer into the condition of patients so affected, and then into the prospects for their future.

The fistulous opening leads (with the exception of a few cases, in which the sole remnant of the empyema is a carious rib) into a cavity between the thorax and the lung—a cavity with fibrous, connective-tissue walls, covered with a layer of soft pus-secreting granulating tissue, and usually without, but sometimes with, connection with one of the bronchi. It is needless to state that the size of such a cavity, and the amount of purulent matter secreted from its walls, may vary indefinitely; but even a small cavity, with a moderate secretion, is not only a constant inconvenience to the patient, but also a fruitful source of danger to his health and life in the course of time.

The patient usually is pale, weak, and unable to perform the ordinary duties of life. From time to time the fistula may close up, and retention of pus, with subsequent pain, exhaustion, and fever, result. In cases where primary tuberculosis, or cheesy deposits in the lung tissue, do not exist, or are at a standstill, the constant suppuration of the cavity, together with the formation of a deposit of cheesy matter, may be the starting-point for tuberculosis, or, by breaking down the patient's general health, may arouse a latent tuberculosis.

But if tuberculosis be not the main danger in these cases, there is another, just as serious, and perhaps more certain sooner or later to ensue, namely, the amyloid degeneration of the kidney, spleen, and liver. In the majority of fistulæ we are liable to find some day, sooner or later, the patient with œdema around the malleoli, a slight amount of albumen in the urine; sure signs that he is approaching the inevitable fatal termination.

The objection might be made here that a number of cases are met with and on record in which, for a long series of years, a discharging thoracic cavity has been sustained without much impairment of the general health, without the development of tuberculosis or amyloid degeneration. But, this being granted, we must confess that in such cases we never know when the fatal complications will commence, whether in a few months or in a few or many years. Consequently we must regard every permanent empyema cavity as a constant menace to the life of the patient.

In view of these considerations it is not only our prerogative, but also our duty, to try every reasonable means for the obliteration of the cavity.

It is not my intention here to discuss the whole local and general treatment of empyemas, the various fluids injected, and so on. This paper is intended to treat only of those empyema cavities where the rational operation has been performed in time, where antiseptic dressing, accompanied by thorough drainage and washing out with the various disinfectant and alterative fluids, has been used; in short, where all other possible means have been exhausted, but the lung will not expand any more, the

thorax cannot sink in any more, and no injection of fluid causes any formation of connective tissue to fill up the cavity; it is in these cases that we are obliged to employ Estlander's operation.

The only way to close an empyema cavity in this condition is to effect by an operation a more or less complete contact of the walls of the cavity. As it is not in our power to act upon the internal or pulmonary wall of the cavity, or in other words, as we are unable to bring the surfaces of the lung out in contact with the wall of the thorax, nothing is left but to obviate the rigidity of the wall of the thorax by taking away, from the ribs covering the cavity, pieces as large and as many as may be necessary to effect a further sinking in of the throracic wall, and sufficiently extensive to bring the latter in contact with the surface of the lung.

Before discussing the details of the indications for the operation, the operation itself, and the after-treatment, I will report the following case as an illustration:

CASE. *Right-sided pleurisy, resulting in empyema; repeated aspiration; inefficient fistulous opening discharging for a year and a half; dilatation of opening, drainage and washing out; no counter-opening; daily washing out for a year; removal of seven centimetres of the sixth, six centimetres of the fifth, and six centimetres of the fourth rib in the axillary region over a transverse cavity two inches long, an inch and a half high, and about an inch deep; slight fever for six days; small subcutaneous abscess below the scar after eighteen days; drainage-tube of cavity removed in thirty-seven days; cavity and fistula closed in fifty-four days.*—Rebecca S., 16 years of age, was admitted to Cook County Hospital, October 11, 1881. Her history was as follows: Her father died of acute consumption at about the age of thirty. Her mother is still living, thirty-four years of age, and enjoys good health. The patient's hygienic surroundings have been relatively good. She had rubeola and whooping-cough in her sixth year, but had no other sickness until two years and nine months before her admission to the hospital, when she had a severe attack of pleurisy on the right side, which kept her in bed for two weeks and terminated in an empyema. Aspiration was employed three or four times by her physician, Dr. Banga, at intervals of about a week, but difficulty was always experienced in drawing off the pus on account of its admixture with fibrinous matter, so that complete evacuation was impossible. One of the openings made by the aspirator needle remained open and discharged a considerable amount of pus daily for a year and a half. During this time, and until a year before her admission to the hospital, she had no medical treatment. At this time her general health began to be much impaired, she lost flesh and appetite, and became weak and anæmic.

On account of this she consulted Dr. E. Andrews, of Chicago, who dilated the already existing opening into the pleural cavity, inserted through this a drainage-tube, and washed out the cavity with carbolic acid solution. The cavity was washed out daily until her admission to the hospital, and in consequence her health improved to some extent.

On admission the patient was found to be small for her age, spare, but not extremely emaciated; she was pale, her appetite poor, and she could not sleep without the use of hypnotics, rather because of her habituation to their use, than on account of any especial pain in the side. The right half of the chest was sunken and flattened; the right shoulder was lower than the left; a slight curvature of the spine in the dorsal region, with concavity to the right, was noticeable, which had resulted, as usual in such cases, from the sinking in of the right wall of the thorax. Two and one-half inches below and half an inch to the right of the nipple, between the sixth and seventh ribs, was a fistulous opening leading upward and backward into the empyema cavity, and into which a probe could be passed five and a half to six inches. The amount of discharge was from one and one-half to two tablespoonfuls daily.

Percussion resonance was clear over the clavicular and in the infraclavicular region, down to about the fourth rib, but dull from this point down to the liver. In the place of the clear percussion, vesicular respiration was somewhat weak, but still could be distinctly heard. On the dorsal side there were clear percussion and vesicular respiration all over the scapula; in the infrascapular region, dull percussion and no respiration sound.

The heart and left lung were normal; temperature and pulse normal; bowels regular; urine light straw-colored, clear, acid, and contained neither albumen nor sugar. There has been no œdematous swelling of the lower extremities at any time.

Daily washing out of the cavity with a two and one-half per cent. solution of carbolic acid was ordered, and a voluminous Lister dressing applied over the fistula. The patient was discharged from the hospital October 15, and ordered to continue the treatment at home.

A month later, November 16, the patient was readmitted to the hospital. During this time the daily discharge had decreased a little, but amounted still to about a tablespoonful. She has become weaker, her appetite poor, and complained of frequent pain in the right side, and headache. The cavity was now washed out daily with a one-tenth per cent. solution of thymol, Lister dressing applied, and quinia and iron given internally.

During December and January this treatment was continued, but no especial improvement was noticeable notwithstanding the injection of different fluids, such as tincture of iodine, alternating with the solutions of thymol and carbolic acid.

In January she came under my care, and I resolved to try the thoracoplastic operation as a last resort to effect the closure of the cavity and check the suppuration. Once more the urine was carefully examined both chemically and by the microscope, and was found not to contain albumen nor casts of any kind.

On January 27, at the surgical clinic in the amphitheatre of Cook County Hospital, in the presence of Dr. W. Meacher, of Portage, Wisconsin, assisted by the hospital staff, I operated in the following manner: The patient having been anæsthe-

tized with ether, was placed on her left side, and the right side of the thorax carefully disinfected with a five per cent. solution of carbolic acid and the nail-brush, the fistulous track was laid open for an inch and a half, when it passed inside the wall of the thorax between the sixth and seventh ribs. The incision was then carried upward and backward, along the outer surface of the sixth rib for about three inches, making the entire incision about five inches in length. By means of a gouge the sixth rib was now denuded of periosteum, and a piece seven centimetres long removed by a bone forceps. In the same manner six centimetres of the fifth rib were removed. After this had been done I was able to introduce the little finger into the empyema cavity, which was found to be two inches long, an inch and a half high, and about an inch deep, extending up behind the fourth rib, the apex being at the third intercostal space. The upper border of the incision could be drawn upward beyond the fourth rib, which I denuded, and then removed a piece six centimetres in length. Having a finger in the cavity and passing the other hand over the covering wall of the thorax, I ascertained that the pulmonary and thoracic walls of the cavity could be brought in contact, and so did not resect the third rib. The walls of the cavity were found to be firm, hard, connective tissue, covered with a layer of flabby granulating tissue. All of the latter was removed by the sharp spoon. The hemorrhage during the operation was trifling, no ligatures were needed, the slight hemorrhage from two of the intercostal arteries being stopped by torsion.

As the upper posterior end of the wound showed a tendency to form a pocket in the loose connective tissue below or anterior to the latissimus dorsi muscle, a buttonhole opening was made through the latter for a drainage-tube, near the angle of the scapula. The wound and the cavity were then thoroughly irrigated with carbolic acid solution, the walls dusted with iodoform, one large drainage-tube inserted into the cavity and another along the entire extent of the wound, from the scapula to the anterior end of the old fistulous tract, the wound united with disinfected silk, and covered externally by a layer of iodoform, over which a voluminous Lister dressing was applied. The carbolic spray was used during the operation which lasted about an hour.

7 P.M. Pulse 136; temperature 99.8°. The patient has vomited a little, but is warm, and, with the exception of the high pulse, presents no evidence of shock.

January 28.—A.M. Pulse 114; temperature 100.6°. Has slept off and on, an hour at a time, from the use of hypodermic injections of morphia. Complains of pain in the side. 7 P.M. Pulse 124; temperature 100°. Complains of pain. Has taken champagne, and a little milk and lime water.

29th.—A.M. Pulse 134; temperature 101°. Has slept for an hour at a time during the night. Complains of thirst and headache. Dressed the wound, which showed slight suppuration, and washed it out with thymol solution. 7 P.M. Pulse 148; temperature 102.5°. Ordered five grains of quinia every four hours, subcutaneous injection of one-fourth grain of morphia when the pain is severe, and potassium bromide and chloral at bed-time, the latter to be repeated if she wakes during the night.

30th.—A.M. Pulse 130; temperature 101.2°. She has slept well during the night, is somewhat nervous and feels feverish, but her general expression is good. P.M. Pulse 142; temperature 102.6°.

31st.—A.M. Pulse 124; temperature 101.5°. P.M. Pulse 130; temperature 102°.

Feb. 1.—A.M. Pulse 108; temperature 100°. P.M. Pulse 106; temperature 100.2°.

2d.—AM. Pulse 120; temperature 98.5°. P.M. Pulse 130; temperature 100.2°.

3d.—A.M. Pulse 106; temperature 99.5°. P.M. temperature 101.2°. Wound dressed and stitches removed, discharge moderate. Patient sleeps better, and has some appetite.

4th.—A.M. Pulse 118; temperature 99.7°. P.M. Pulse 120; temperature 101.7°.

5th.—A.M. Pulse 128; temperature 99°. P.M. Pulse 112; temperature 99.5°.

6th.—A.M. Pulse 114; temperature 99°. P.M. Pulse 120; temperature 100.6°.

7th.—A.M. Pulse 110; temperature 99.2°. P.M. Pulse 108; temperature 100°.

8th.—A.M. Pulse 104; temperature 98°. P.M. Pulse 103; temperature 99°.

9th.—A.M. Pulse 120; temperature 99.2°. P.M. Pulse 118; temperature 98°.

10th.—A.M. Pulse 112; temperature 99.8°. P.M. Pulse 122; temperature 100.6°. Outer drainage-tube removed; very little discharge.

11th.—A.M. Pulse 120; temperature 98.5°. P.M. Pulse 108; temperature 99.8°.

12th.—A.M. Pulse 110; temperature 98.7°. P.M. Pulse 124; temperature 99.6°.

13th.—A.M. Pulse 120; temperature 99.8°. P.M. Pulse 126; temperature 101.2°.

14th.—A.M. Pulse 120; temperature 100.7°. P.M. Pulse 128; temperature 101.1°. The rise in temperature was accompanied by pain in the region of the wound and headache. She did not sleep well during the night, and complains to-day of considerable pain in the side. On the removal of the dressing a fluctuating swelling was found just above the centre of the united wound. As the contained pus could not be pressed out through the drainage-tube in the old empyema cavity, a small incision was made, though which about an ounce of somewhat fetid pus was evacuated, A small drainage-tube was now inserted, and the cavity washed out with a two and one-half per cent. solution of carbolic acid.

15th.—A.M. Pulse 114; temperature 98.2°. Patient has slept well during the night, and the fever and pain have subsided.

21st.—Very little discharge; removed the small external drainage-tube, and shortened the internal drainage-tube an inch.

March 5.—Discharge scanty; removed internal drainage-tube, and replaced it by sticks of iodoform and gum arabic, equal parts.

21st.—Patient had headache and rise of temperature last night. No pain in the side. The wound is superficial and granulating. There is nothing to

be found in the thorax to account for the transient rise in temperature.

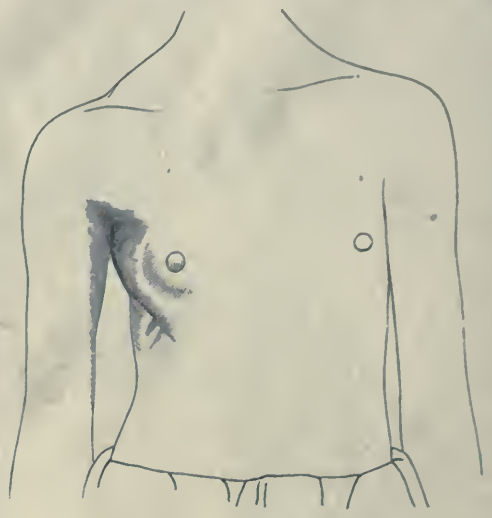
22d.—The patient was discharged from the hospital cured.

August 8.—The patient came to my office. Her condition was then as follows: The right shoulder was an inch lower than the left. The right clavicle half an inch lower than the left. The right angula scapulæ three-quarters of an inch lower than the left. The arms being in a corresponding position, the distances from the spines of the vertebræ to the medial margin of the right scapula were, in the upper half, two, and in the lower half one and one-half inches; to medial margin of the left scapula, three inches. When the elbows were pressed against the crest of the ilium, the left arm was at all points in contact with the lateral wall of the thorax, but between the right arm and the lateral wall of the thorax, there was a space of three-quarters of an inch in the centre and half an inch at the axilla and above the crest of the ilium. The lower margin of the right pectoralis major had a horizontal portion one and one-quarter inch in extent; the left had none, or only about a quarter of an inch. About the nipple the circumference of the left thorax was thirteen and a quarter inches; of the right, ten and three-quarters inches, measurements being made below the angle of the scapula. At the axilla the circumference of the left thorax was thirteen and three-quarters inches; of the right, eleven and three-quarters. In the region of the eleventh dorsal vertebra the circumference of the left thorax was twelve and a half inches; of the right, ten inches. The anterior surface of the sternum was turned to the right. The deepest sinking in of the right pleural cavity was at a point just above the nipple, corresponding to the fourth rib, where the antero-posterior diameter was three and a half inches; at the corresponding point on the left side, the diameter was five inches. Immediately below the clavicle, the antero-posterior diameter on the right side was three inches; on the left, three and three-quarters inches.

On the right anterior side there was clear percussion to the fourth rib, below this point, dull; in the axillary region clear percussion to the fifth rib, below this point, dull. On the posterior side percussion in the supraspinatous, infraspinatous, and interscapular regions, was clear; in the infrascapular region, dull. There was vesicular respiration on the anterior side in the place of the clear percussion, and on the posterior side, except in the interscapular region, where the respiration had a hollow, bronchial character.

On the left side there was clear percussion down to the third rib, where the heart dulness commenced, extending from the left border of the sternum to the region of the nipple, where, between the fourth and fifth ribs, the apex beat was perceptible. The heart and left lung were perfectly normal.

The scar, shown in the accompanying cut, was four inches long, extending from two inches below the right nipple, at about the sixth rib, upward and backward to the anterior border of the latissimus dorsi. Two inches behind and above the upper end of the scar, was the cicatrix of the buttonhole opening for the drainage-tube.



In the dorsal region there was a slight curvature of the spine, the concavity to the right, the centre of the concavity being at the eighth or ninth dorsal vertebra.

The patient has had monthly attacks of migraine, but neither pain in the chest nor cough.

The ends of the resected fourth, fifth, and sixth ribs, could be plainly felt, but between them the wall of the thorax was so resistant that it was evident that formation of osseous tissue had taken place.

The patient's general condition was good. Her appetite was better than when the fistula was open, and she was not anæmic.

From the beginning the empyema in this case was undoubtedly a total one; that is, it involved the entire pleural cavity, as was shown by the very considerable uniform diminution in size of the whole right thoracic cavity, which amounted to two and two and a half inches in the circumference, and from three-quarters of an inch to an inch and a half in the antero-posterior diameter of the thorax. As far as the extent of the empyema was concerned, this was one of the grave cases, and it is not surprising that even, as in this case, in a child less than fourteen years of age, the flexibility of the thoracic wall should not be sufficient to permit the sinking in necessary to bring it in contact with an almost entirely compressed lung. It is probable, however, that at the age of this patient, if the empyema had been properly treated from the beginning by timely incision and drainage, the lung, freed from the constant pressure of the large quantity of fluid contained in the cavity, might have been able to expand before the covering layer of connective tissue had become too thick and firm, so as to meet the wall of the thorax, and consequently a permanent cure might have been effected earlier, and a larger amount of lung-tissue made available for future use. This is the more probable, as in none of Estlander's cases was the thoracoplastic operation necessary in patients under twenty-one years of age, and it is certain that only in a child could such a remarkable diminution

in the size of the thoracic cavity, as was seen in this case, have been possible.

In my case, the effect of the operation, namely, the closure of the cavity and fistula, was very prompt, taking place in fifty-four days after the operation, or in twenty-two days less than Homén's average. This was to be expected, as Estlander's patients were older.

The immediate result of the operation was plainly to be seen in the remarkable sinking in of the thoracic wall in the region of the nipple, that is, over the fourth rib, where the antero-posterior diameter was lessened an inch and a half.

The idea of resecting pieces of the ribs in empyema is not a new one, as more than twenty years ago Roser advised the excision of a piece of a rib, three to six centimetres long; in order to get access to an empyema cavity and to avoid trouble in keeping the fistula open. For this purpose excision of the ribs has been in general use in surgery for a number of years, and is practised everywhere. Homén states that an American surgeon named Walter (*British Medical Journal*, January 2, 1860), in 1857, resected an inch of the eighth rib in a case of intractable fistulous empyema, because he thought that caries of the rib might possibly be the cause of the suppuration. As no improvement took place, two months later, he resected two inches each of the eighth and ninth ribs for the same purpose. The fistula closed up a year afterward.

It is thus evident that Walter had made a thoracoplastic operation, but without being exactly aware of the idea of the procedure. Simon, in 1869, was aware of the fact that after resection of a rib for empyema, the cut ends of the bone soon approached each other, and he laid stress upon the fact as a means of diminishing the size of the empyema cavity.

Heineke, in 1872, proposed to remove a piece of the rib covering the fistula, seven centimetres in length, for the same purpose.

To Estlander belongs the undisputed merit of having systematized the operation, extended it to the resection of as large a number of ribs as the size of the cavity may require, and reported a series of eight operations (*Revue Mensuelle de Médecine et de Chirurgie*, February, 1879); in fact, Estlander has proved not only the practicability of the method, but also its great value. In reality the operation is Estlander's, and it, therefore, seems proper to accept the name, thoracoplastic, given it by him.

Indications for the Operation.—As already stated above, the thoracoplastic operation will have to be resorted to in cases of intractable empyema cavities that have resisted all other treatment. But the question arises: When in the course of such an empyema is it time for the operation? Naturally it is impossible to fix a stated time that will apply to all cases and ages, but Estlander strongly advocates that the operation shall not be made early, as he considers it a *conditio sine qua non* for a beneficial result of the operation that both the pulmonary and costal pleuræ shall have been tranformed into a thick layer of firm connective tissue, with its great inherent retractive power. Homén gives, as an approximate rule, that when the fistula has existed four or five months without any diminution of the cavity, the operation should be resorted to. As the disease has probably existed for two or three months before the fistula, the time for the thoracoplastic will be six to eight months after the beginning of the disease.

The fact that the cavity is not diminishing in size should be ascertained by careful watching of the patient; when the successive injections into the cavity show the quantity of the injected fluid to be the same, and when, on probing the cavity with uterine sound or metallic catheter its dimensions are found to remain materially the same.

It is a question, however, if it would not be appropriate to operate somewhat earlier, as Homén has stated that the earlier the empyema operation is performed, the more quickly will the fistula heal up in favorable cases, and it is evident that the thoracoplastic operation is liable to be more effectual when the layer of connective tissue covering the lung and the wall of the thorax is of moderate thickness, instead of being firm, hard, thick, and unyielding in any direction. Furthermore, one of Estlander's main arguments for delaying the operation until the pleura has been transformed into a thick connective-tissue membrane, is this: That the pleura has lost its character of serous membrane, and thus the danger of opening into a pleural cavity is obviated.

His reasoning here is not quite correct, because at no period of an empyema is there any danger from opening the pleural cavity under antiseptic precautions in adults, and besides, if the empyema cavity be local, that is, only a part of the whole pleural cavity, there is no likelihood of opening or cutting into healthy parts of the pleural cavity during the operation, as the adhesions necessarily surrounding the empyema cavity will probably always be extensive enough to prevent such an accident, and in most cases no serous or healthy parts of the pleural cavity will be found at all.

As contraindications, advanced tuberculosis of the lung, albuminuria, and extreme debilitation of the patient naturally present themselves. Of the first two named, the albuminuria from amyloid kidney is probably the most important, as such patients are liable to succumb to the shock of even a not very serious or long operation. As to the third contraindication, the debilitation of the patient, Estlander has shown, that in patients emaciated almost to a skeleton, and so weak that they could take only a few steps, and in one in which the patient was so weak that he could hardly turn himself in bed, the operation has caused very slight transitory derangements in the patient's condition, and that the slight fever and pain following the operation have disappeared in a few days, to be followed by a remarkable, almost constant, improvement. It is thereby shown that the operation is by no means an exhausting one, but may be resorted to in cases where the patients are extremely debilitated.

Operation.—In deciding upon the plan of operation in each special case, the first consideration is naturally the shape and size of the cavity, and the plan will be essentially different when the cavity

has its greatest length from above downward in a perpendicular direction, and when its direction is transverse from before backward. A longitudinal cavity covered by five, six, or seven ribs, and not extending from the sternum to the vertebral column, but only occupying part of the thoracic cavity, will usually have the greatest depth in the axillary and infra-axillary regions, and will require the resection of small pieces, that is, from two to six centimetres, of a large number of ribs. In one of Estlander's cases, in two successive operations, two to six centimetres were resected of not less than nine ribs, from the third to the eleventh inclusive.

The first and second ribs are, as a matter of course, so inaccessible, and, also, so near the large vessels, that they are out of the question for resection. The twelfth rib is too short and too movable to ever require the operation.

A transverse cavity requires the resection of a larger piece of one or a few ribs. As to the length of these pieces, Homén, from a rather theoretical point of view, by mathematical deductions, gives the rule that there should be resected of each rib a piece, the length of which is equivalent to the greatest distance between the inner surface of this rib and the pulmonary surface of the cavity. Consequently, of several ribs covering the cavity, the largest piece will have to be resected from the rib extending over the middle of the cavity. In the main, these theoretical deductions will be found practically applicable.

The most important muscles interfered with are the pectoralis major and the serratus anticus major. When the resection is made strictly subperiosteal, there will be the same rehabitation of functions of these muscles as in the subperiosteal excisions of joints, a more or less extensive formation of new bone always taking place in the periosteal sac of the excised ribs.

The incision varies according to the number of ribs to be resected. For the excision of long pieces of two or three ribs, one single incision parallel to and either between the two, or along the middle rib of the three, will give sufficient space for the removal of the pieces, especially when by sinking in of the thorax the ribs are in more or less close approximation to one another.

For the excision of small pieces of a large number of ribs, it is best to make several incisions parallel to and above each other in the intercostal spaces, each incision permitting the excision of two ribs. Estlander attempted in such cases to make one vertical incision for the resection of several ribs, but found it inconvenient, as he was obliged to make several secondary incisions at right angles to the first, and so made an irregular wound, requiring several drainage tubes, and slow and somewhat difficult to heal.

Through the incision in the skin, the periosteum is divided along the external surface of the rib and stripped from the latter by a common gouge. This is usually accomplished without difficulty. Occasionally it is rendered more difficult when, by sinking in of the thorax, the ribs are pressed together, and sometimes even overlap. To perform the operation in such cases it would be necessary to commence with the most superficial rib of course.

As a matter of course, the ribs should not be denuded of periosteum beyond the location of the piece to be excised, with the view, as Homén states, of avoiding necrosis of part of the resected rib. Fear of such a necrosis would be unnecessary if all excision wounds healed by first intention. But this will, as a rule, not take place, because the wound is in connection with an already suppurating cavity, from the walls of which, by the most careful scraping out, all of the inflammation-producing germs cannot be removed.

The hemorrhage is always insignificant; Estlander has never been obliged to make a single ligation.

If the cavity is small and the walls sufficiently firm, it may be well to remove the soft suppurating layer of granulations with the sharp spoon, providing the cavity is so situated that no important organs are thereby endangered, for the following reason: If the thoracoplastic operation is sufficient to produce perfect approximation of the walls of the cavity, the scraping out might make closure by first intention possible.

A counter-opening from the cavity to the posterior wall of the thorax at the latissimus dorsi muscle is desirable, if not necessary, if the cavity is of considerable size.

The external wound should, of course, be united, drained, and dressed antiseptically.

The after-treatment lasted generally about ten weeks in the cases in which recovery took place. The fever following the operation was always moderate. The rather constant and more or less violent pain in the operation wound was remarkable. It usually lasted only for a few days, and was easily overcome by morphia.

The wound should be dressed every two to four days, according to the amount of discharge, accompained by washing out with antiseptic fluids through the drainage-tubes. How far the theoretical rational advice of Homén to assist the sinking in of the thoracic wall operated upon, by local pressure upon it, is practicable, cannot yet be stated. In my case it was impossible to resort to this measure, because of the pain in the side, which did not permit me to apply the common dressings even as firmly as I wished, but obliged me to apply the roller bandages as loosely as possible and still hold the dressings in place.

An important question during the after-treatment is to determine the progress of the diminution of the cavity, by means of the quantity of fluid injected and the probe. When it is found that a cavity comes to a standstill, a second or even a third operation may have to be resorted to. The time between the two operations in the same case has varied from six weeks to five months.

The thoracoplastic operation should undoubtedly be accepted as a valuable, if not a necessary, final step in the treatment of empyema, a general view of which would be nearly as follows: As soon as the diagnosis of an empyema is thoroughly established, aspiration should be first resorted to if the pus in the pleural cavity is not fetid. If after repeated aspira-

tions the fever does not decrease, nor the lung expand, and the cavity refills rapidly, the empyema operation by incision *in loco selecto*, and counter-opening in the lowest part of the cavity, with resection of a piece of rib if necessary, and thorough drainage and washing out, is in order. This operation should be performed as early in the disease as possible, as the statistics have shown that the earlier it is performed, the better are the chances for recovery.

Finally, if this operation does not procure complete recovery, that is, complete closure of the cavity within about six months, the thoracoplastic operation should be performed, and if necessary be repeated until perfect recovery is obtained.

Estlander has established beyond doubt that some lives, otherwise lost, may be saved by this operation, and I am glad to do honor to the memory of a man with whom I have been in friendly relations in former years, and whose premature death is a deplorable loss to science, by bringing his operation before the notice of the profession of this country.

120 W. INDIANA ST., CHICAGO, ILL., July, 1882.

A CASE OF BRONCHITIS IN A NEW-BORN INFANT—DEATH ON THE THIRD DAY.

BY ANDREW F. CURRIER, M.D.,
OF NEW YORK.

MOST of the diseases of fœtal life must forever remain obscure. When the mother is apparently in good health during the months of utero-gestation, and comes of good lineage, we look for healthy offspring. (Of course infectious diseases are excluded in this statement.) The child is beyond the power of clinical observation until it comes into the world, and then the physician is occasionally so heavily handicapped that his efforts to assist the sufferer are unavailing. Such is the case in bronchitis neonatorum. Vogel says the patients usually die.

Mrs. E. E., the mother of the child is of Welsh birth, twenty-one years of age, has always been healthy, and comes from a healthy family. Her mother had nine children, all but the last of which were delivered with the assistance of a midwife only. Her last menstruation was in September, 1881, and with the exception of constipation and some slight pain in the left side and leg during the latter months, she suffered no inconvenience during her pregnancy. Labor began at 4 A.M., June 9th, when she was awakened from sleep by the breaking of the fœtal membranes and the escape of the waters.

When I saw her a few hours later, she was having occasional pains, of no great force; the os was sufficiently dilated to admit the ends of two fingers, the vaginal tube was soft and well lubricated, and the head presented above the brim in the first position. Labor progressed rather slowly, but the patient had an abundance of strength, and would not permit the application of the forceps. The head was delivered without accident at 2 P.M., and as the uterine contractions then became very weak, some force was required for the removal of the body. Respiration was secured after a few moments of effort, though the child was deeply cyanosed at birth.

After expressing the placenta, it became necessary to peel off the membranes, which were adherent at the lower segment of the uterine body. Quite a copious hemorrhage followed, which was checked by firm and persistent pressure upon the uterus, after which the organ contracted properly. The placenta was of about the average size, and healthy in appearance. The cord was centrally inserted, was of average length, but of small calibre. The membranes were soft and easily torn.

The child was a fairly developed male, weighing about seven pounds. The frænulum linguæ extended nearly to the tip of the organ, and this was cut away without any resulting hemorrhage. Within half an hour after birth the child had a spasm, and became deeply cyanosed. I removed a quantity of thick mucus from the mouth and throat, but supposed it was nothing different from what one frequently finds in the mouth of new-born infants. In a few minutes the spasm and cyanosis recurred. He was put into hot water, and more mucus removed from the mouth. As he seemed tolerably comfortable after recovering from this attack, was breathing fairly well and seemed to have a proper circulation, I hoped he would have a comfortable night. In this I was disappointed, for there were several attacks of dyspnœa during the night.

The next morning the pulse was not more rapid than is usually found in so young an infant; the skin was of good color, but the breathing was very rapid. Mucous râles could be heard over the lower lobe of each lung, particulary the right one. The child was placed at the breast, and the mother said she could feel suction. Small doses of carbonate of ammonium dissolved in simple syrup were ordered every two hours, and as the mucous membrane of the lips and nose were becoming dry, sweet oil was placed upon them.

The next day when I called the child was very weak, breathing rapidly and with difficulty, and in a semi-unconscious condition. He had resisted all attempts to introduce anything into his stomach, choking violently each time. Death took place about fifty hours from birth. The father consented to an autopsy, but upon reaching the house I found the mother violently opposed to it. As she was excited and feverish, it would have been unwise and improper to press the matter, so that the question as to the absolute condition of affairs remained unsolved.

Whether the foramen ovale was closed, whether there was atelectasis or a simple catarrhal bronchitis, which was not diffuse, excepting over the lower lobe of each lung, I was unable to find out by inspection of the parts. From the facts which have been stated, I am inclined to the last-mentioned view of the case.

The subject of congenital bronchitis is not dwelt upon by any of the writers upon children's diseases, which I have been able to find. They all describe bronchitis, and Bouchut has stated that it may be present from the moment of birth. He considers general bronchitis, capillary bronchitis, and bronchopneumonia, as synonymous. Smith, and Meigs and Pepper would probably refer this case to atelectasis,

which is described with great clearness. Gerhardt, Vogel, and Rilliez and Barthez, strengthen the diagnosis made, without saying anything positive about the congenital existence of the disease. The older writers, Churchill, Tanner, Hölder, Condie, and others, make little or no reference to the disease among the newly-born. Tanner, as the result of his own observation and the published statements of Billiard and Valleix, thinks that the influence which age has upon the disease is difficult to state precisely, especially with reference to the newly-born. He has not often seen it among infants at the breast, and thinks it rare.

HOSPITAL NOTES.

VIENNA GENERAL HOSPITAL.

(Service of PROF. SPAETH.)

"CONGLUTINATIO ORIFICII UTERI;" DILATATION, HYSTEROSTOMATOMY.

(Specially reported for THE MEDICAL NEWS.)

A CASE of "conglutinatio orificii" (Nägele) has recently been observed in the lying-in-rooms of the second obstetrical clinic.

The patient, white, Austrian, unmarried, thirty-two years old, brought into the ward August 17, was in her first pregnancy, and had felt labor-pains for the three preceding days. The course of her pregnancy was of a normal character. Abdominal palpation revealed pregnancy at full term, vertex presentation, first position (Vienna nomenclature). Heart sounds were loud, regular, and perfectly normal; vaginal examination showed the fornix vaginæ to be of orbicular shape and well pressed down into the canal. The small fontanelle was felt, through the fornix vaginæ, to the left and behind, constituting a vertex presentation, first position. No cervical portion or external orifice could be perceived. Finally, the finger touched a depression toward the anterior portion of the fornix, which, upon examination with a Sims' speculum, proved to be the position of the external orifice. Roundabout this little depression very tender radiating cicatrices were noticeable; its centre was a papilla of a strawberry appearance, resembling granulation tissue. The orifice of the uterus was covered with a lamella, which was so tough that it could not be broken up by the fingers. Accordingly, Simpson's sound was passed through it, and dilatation effected by means of a bougie first, and a pair of dressing-forceps subsequently. Still later, two fingers were introduced and the external orifice was stretched to the extent of two cm. The whole operation was exceedingly painful, as no anæsthetic was administered. During the dilatation the bag of waters was ruptured. Three hours later the external orifice had made very slight progress in dilating, while the woman was experiencing very strong frequently recurring pains. The cicatricial constricting fibres of the cervix were then divided in seven or eight places with a button-pointed bistoury. This operation was also accompanied by great pain, while the hemorrhage was insignificant.

One-half hour later, the birth reached its terminus. The child was a girl, mature, in good condition, weighing 3150 grms., and with a length of 50 cm.

"Conglutinatio orificii" has occurred about once in a thousand cases in the wards of Prof. Spaeth. The cause of the affection, according to Prof. Carl Braun, is either an abnormally short vaginal portion, which permits the mucous membrane of the fornix vaginæ to grow together, occluding the orifice, or a croupous or local inflammation of the external orifice, as above, or of the cervix, leading to the formation of cicatrical connective tissue, with subsequent contraction and obliteration of the orifice alone, or of a portion of the cervical canal. The first condition, the occlusion of the external os, is termed by Nägele, "conglutinatio orificii;" the second condition, the oganic connection of a portion of the mucous membrane of the cervix with the vaginal portion, is termed by Schmitt "conglutinatio organica." Prof. Braun is of the opinion, gathered from his immense experience of twenty-five years in the greatest obstetrical school in the world, that it is never necessary to make a bloody opening of the mouth of the uterus in case of "atresia orificii."

MEDICAL PROGRESS.

THE FILLET IN BREECH PRESENTATIONS.—DR. HEINRICH V. WECKBECKER-STERNFELD, assistant physician to the lying-in institution at Munich, contributes to a recent number of the *Archiv für Gynäkologie* a paper on the above subject. He points out that there are cases in which some help is required, in which traction by the unaided finger is inefficient, and bringing down a leg difficult and not devoid of danger. The blunt hook cannot be used without much risk of injuring the child; the forceps are apt to slip, and, indeed, can only get a hold by strongly compressing the pelvis. There are, therefore, cases in which traction by the fillet or loop is called for. The object of the paper, and our reason for quoting it, is to describe a new instrument invented and recommended by Professor Hecker, of Munich, for the purpose of getting the loop into position. It consists of a blunt hook having a very obtuse curve, somewhat that of a bladder-sound, and hollow from end to end. In this travels a steel spring, like that of Bellocq's instrument for plugging the nares. The tape (or strip of whatever material is preferred as a means of traction) is provided with a little pocket at one end, into which the extremity of the blunt hook fits. It is thus carried by the hook up on the outer side of the hip-joint, and over the the fold of the groin. The spring running inside the hook is then pushed forwards, made to protrude from the end of the hook, and of course carry before it the pocket on the end of the strip of tape. The elasticity of the spring makes it curl round the thigh, and then, of course, the end of the tape can be seized and drawn downwards, and an efficient means of traction is thus secured. The author gives an account of twelve cases in which this means of delivery was used. As the chief objection commonly urged against it is the risk of injury to the fœtus, we quote the results from this point of view. Four times deep pressure-marks were found; twice superficial excoriations. In one case a fracture of the humerus was produced in drawing down the arm, and twice fracture of the femur—in one case made in an unsuccessful attempt to bring down a foot, in the other during extraction by the loop. No maternal bad result was noticed, except in one case rupture of the perineum during extraction of the shoulders.—*Medical Times and Gazette*, September 2, 1882.

CAFFEIN IN HEART DISEASE.—The use of caffein has not become general in this country as yet. In England it has attracted some attention as a diuretic, and it has been used to some extent as a nerve tonic, Dr. Shapter having specially commended it in the treatment of nervous diseases dependent upon the abuse of alcohol.

Professor Lépine, in a recent paper in the *Lyon Médicale*, urges the use of caffein in the treatment of heart diseases, in the same class of cases in which digitalis is usually found valuable. He thinks that caffein pos-

sesses distinct advantages over digitalis, which he considers in detail.

He has been using caffein in these cases for four years, and has administered it to more than sixty patients. He maintains that the dose, to be effective in action upon the heart, must be considerably larger than that which has ever been generally administered heretofore. He gives from 60 centigrammes (9.25 grains) to 1.5 gramme (23 grains), and sometimes 2 grammes (30 grains), or even 2.5 grammes (37 grains). Such doses as are directed in the books he finds utterly inefficacious.

He found that this drug is equally effective with digitalis in retarding the rate of cardiac action and in increasing its force. In comparing the relative merits of the two drugs, he asserts that caffein acts much more rapidly than digitalis, which fact, though it may be of little importance in a chronic disease, may be of real importance where asystolia occurs as an acute condition. Secondly, he says that caffein is much better tolerated than digitalis, and if taken in divided doses during the day very seldom causes any symptoms of intolerance at all, such as are not at all infrequent in the administration of digitalis. This he attributes to the facility with which caffein is eliminated. Of course, where the kidneys fail to eliminate the drug it would be retained in the system, and would occasion disturbance, but he claims that the danger from this source is far less than that from the use of digitalis. Finally, he has found that by the majority of patients the caffein is preferred to the digitalis. He has repeatedly found this to be so in cases where he has used both drugs alternately upon the same patient.

On the other hand, there is a certain proportion of patients (he has found this true in about one out of twenty) in whom caffein produces insomnia and other nervous symptoms. While these cases are rare they do occur, and this condition is an absolute contra-indication to the use of this drug.

M. Lépine does not claim that caffein will cure all cases of asystolia, but does assert that it has all the merits of digitalis and some advantages over that drug. He promises to give reports more in detail of his own observations and of cases that have been reported to him by some of his colleagues.—*St. Louis Courier of Medicine*, September, 1882.

Inter-crico-thyroid Laryngotomy.—Dr. Launy (*Lyon Médicale*, June 12, 1882) deals exhaustively with this operation in a pamphlet issued by him within the last few months. The merits of the operation have been repeatedly discussed by various surgeons, but the objections to it have never been sustained by exact anatomical data. M. Krishaber, on the contrary, has proved that in the adult the crico-thyroid membrane was sufficient to admit the introduction of a suitable canula. Dr. de Launy has undertaken measurements on dead subjects, and he has been able to obtain a maximum space of from 12 to 14 millimetres in the adult—2 or 3 millimetres may be added by removing the cricoid cartilage. In the child, laryngotomy is scarcely possible except when over 12 or 13 years of age, when the crico-thyroid space measures at least 7 millimetres.

The operation is easy and clearly indicated. The author strongly advises the employment of the thermo-cautery of Paquelin. By operating slowly and at a dull red heat no bleeding of any consequence occurs. The vertical incision is sufficient and preferable; it permits the introduction of the canula without requiring previous dilation.

A complication accompanying inter-crico-thyroid laryngotomy is a dysphagia which occurs on the day of or the day after the operation, and lasts from eight to nine days. It is probably due to the pressure exercised upon the anterior wall of the œsophagus by the convexity of the canula.

He discusses the indications for and against the operation. It should be performed when the patient's life is in danger. One ought immediately to operate in pseudo-membranous laryngitis, œdema, burns of the larynx, or where foreign bodies are present. Sometimes laryngotomy is alone possible; for example in swelling of the vessels of the neck, in tumors which displace the trachea, and above all, in affections of the thyroid body. In this last case, it is advisable occasionally to overcome the obstacle by replacing the internal canula by an œsophageal catheter.

This operation is, nevertheless, contra-indicated when the lesion renders the crico-thyroid space insufficient to admit an ordinary canula. It is formally forbidden under the age of 12 years, and in the aged, whose crico-thyroid articulations are quite anchylosed.—*Glasgow Medical Journal*, September, 1882.

Strangulated Hernia: Wound of Intestine.—A woman, aged 35, who had for many years had a right inguinal hernia only imperfectly kept up with trusses, and who three months previously had had an abscess over the hernial sac, was admitted into the Necker Hospital under M. Trélat with all the symptoms of strangulation of the hernia. As taxis had already been tried, M. Trélat had her at once anæsthetized, and, after a further attempt at taxis, operated. On opening the sac he found the intestine bound to the sac by old adhesions. He proceeded to dissect through these adhesions, and while so doing the gut ruptured. The dissection was proceeded with, and then the wound in the intestine was closed with seven interrupted sutures, and, after careful cleansing of the parts, the gut was returned, the sac excised, and the wound closed by deep and superficial sutures. Next day the patient passed a motion. The wound healed by first intention, the drainage-tube was removed on the fourth day, and the patient recovered without any complication. This case is very encouraging, for the congested state of the intestinal walls was not favorable to rapid healing of a wound in it or to tolerance of sutures.—*Lancet*, September 2, 1882.

Gall-stones Discharged through an Abscess in the Right Groin.—At a recent meeting of the Cambridge Medical Society, Mr. Wherry related a case of gall-stones discharged through an abscess in the right groin. It occurred in a woman, under his care, who had an obscure swelling in the right inguinal region: an exploratory puncture discovered pus too thick to flow through the canula, but a free incision let out thick pus and over a hundred gall-stones. The finger passed into the wound in the direction of the gall-bladder; a large drainage-tube was then tied in the opening, through which gall-stones still pass. There was no bile, and no fecal odor. The patient had a remarkable history. She was for several years subject to attacks like ague. One year ago she first noticed in the right side of the abdomen a swelling, which enlarged painlessly until it could not be spanned by her hand; her bowels were regular, and she had no jaundice. Two months later the swelling appeared, from her description, to burst inside her, and she was immediately seized with violent cramp-like pains in the right lumbar and iliac regions. The swelling diminished, and she had now attacks of vomiting of dark fluid every five minutes for five days, and during this time she ate nothing; but when the vomiting ceased she had a ravenous appetite, and was able to walk about. Altogether she had five similar attacks of vomiting, lasting from three to five days each, followed by several weeks of health.

Mr. Wherry mentioned a case of three fistulæ from the gall-bladder which led respectively to the duodenum, colon, and skin. A biliary fistula has been known to communicate through the open urachus with the urinary bladder. Gall-stones are reported to have been found in the right bronchus and in the portal vein. Cases of biliary fistulæ opening externally are said by Murchison to occur usually in women, and to be caused by gall-stones, and even when connected with cancer, either worms or gall-stones are also found. In reply to Professor Humphry and Dr. Paget, Mr. Wherry said that he thought there must have been an abscess near the fundus of the gall-bladder into which the gall-stones were discharged after adhesions in the neighborhood: that as there were no jaundice and no pain the inflammation was limited to the gall-bladder and cystic duct. No bile came through the external wound, and the patient had a prospect of complete recovery. Columbus mentions that in the case of St. Ignatius Loyola a gall-stone was found in the portal vein, and an undoubted case has been recorded lately.

Dr. Paget mentioned the case of a lady he had seen some years ago in a desperate state of illness, when there was great pain and tension of abdomen; and when an incision was made, no less than 160 gall-stones escaped, though not all at once. In this case the patient recovered and lived for years. He referred also to another case, in which the patient passed a big stone, but died from cancer of the liver.—*Med. Times and Gaz.*, Sept. 2, 1882.

THE PHYSIOLOGY OF SECRETION.—DR. GAMGEE delivered an interesting address on the growth of our knowledge of the function of secretion before the Biological Section of the British Medical Association. The following are his general conclusions. The complicated studies of the physiology of secretion have brought into greater prominence the dignity, if I may use the expression, of the individual cell. The process of secretion appears as the result of the combined work of a large number of these units. Each, after the manner of an independent organism, uses oxygen, forms CO_2, evolves heat, and derives its nutriment from the medium in which it lives, and performs chemical operations of which the results only are imperfectly known to us, and which depend upon peculiar endowments of the cell protoplasm, of which the causes are hidden from us. So long as the protoplasm is living, the gland cell retains its power of discharging its functions, and in many cases does so, so long as the intercellular liquid furnishes it with the materials required. In some cases, however, the gland cells are specially sensitive to a variation in the composition of the nutrient liquid, certain constituents of which appear to stimulate the protoplasm to increased activity. In the higher animals, the cells, particularly in certain glands, are in relation to nerves which, when stimulated, affect in a remarkable manner the transformations of their protoplasm, leading to an increased consumption of oxygen, an increased production of carbonic acid, an increased evolution of heat, and an increased production of those matters which the cell eliminates and which constitute its secretion.

This historical survey of the growth of our knowledge of the process of secretion exhibits the characteristic features of biological advancement. Comparative anatomy has been the foundation of, observation of facts and physical experiment the road to, physiological research. At various stages the value of hypotheses has been well illustrated, and whenever they have had to make way for the broader and truer interpretations suggested by the accumulation of facts and greater precision of observation, it has been demonstrated that the process of observation is not one of simple sight, but of complex ratiocination.—*Lancet*, Sept. 2, 1882.

CEREBRAL PHYSIOLOGY; THE CROSSED ACTION OF THE BRAIN AND MEDULLA.—DR. BROWN-SÉQUARD has continued his vigorous criticism of modern neurological theories in another communication to the Académie des Sciences. He pointed out that these doctrines rest upon two kinds of proof, to one of which his paper was devoted—namely, to the evidence which has been drawn from the phenomena observed when various parts of the cerebrum are irritated; phenomena which consist chiefly in movements of the limbs on the opposite side. The foundations of the doctrine that movements of one-half of the body are innervated from the opposite half of the brain have been considerably strengthened by the experimental and clinical facts on which the theory of psycho-motor centres rests. But to this doctrine Dr. Brown-Séquard states that his own experiments are absolutely opposed. The numerous researches which he has undertaken during the last four years, seem to him to involve conclusions exactly contrary to the opinions which are universally received. For example, against the assertion that the irritation of the motor region of the brain uniformly produces movements in the limbs on the opposite side, he opposes certain experiments of his own. These show that irritation of one side of the pons Varolii or of the medulla, even of the anterior pyramid, causes, eight or nine times out of ten, movements of the limbs on the same side, and the same effect is observed when, after a transverse division of one-half of the medulla, the superior part of the pons is stimulated, mechanically or by electricity, in the part considered as a motor. Irritation of the cerebral peduncle in the part considered as motor often causes movements of the limbs on the same side. This result occurs five or six times in ten when the peduncle is irritated in its inferior part, and two or three times in ten when the stimulation is applied to the upper part. If the fibres are galvanized which pass from the corona radiata or corpus striatum to the peduncle, movements are often observed on the corresponding side of the body. If these parts are divided transversely on the right side or on the left, the mechanical excitation thus produced rarely causes movement, but when it does the effect is usually manifested on the same side as the irritation. Even stimulation of the motor zone of the cortex, as Couty has shown, sometimes causes movements on the corresponding side. Moreover, Dr. Brown-Séquard has repeatedly shown that if this zone is galvanized, after the lateral half of the medulla or of the pons Varolii is divided, the movements in the opposite limbs, instead of being prevented by this section, occur with still greater force than before the division of those conductors which have been believed to be alone capable of transmitting the stimulation of this zone to the limbs.

According to received doctrines, if one lateral half of the cervical cord is divided at the level of the second pair of nerves, and different parts of the brain are then stimulated mechanically or electrically, on the same or on the opposite side to the spinal lesion, no movement should occur, or only a very slight movement in the members on the same side as the lesion. But Dr. Brown-Séquard finds that under these circumstances, stimulation of the brain causes energetic movements of the limbs, such as a "bipedal" movement, diagonal or lateral, to right or left, or a movement of three, or even of four limbs. He concludes from this that one-half of the cord will suffice to transmit to the limbs, on both sides of the body, the excitation caused by stimulation of the opposite half of the brain.

According to received doctrines the transverse section of the two lateral halves of the base of the brain, the

one section at a distance of one centimetre above or below the other, ought to destroy all or almost all communication between the spinal cord and the portions of the brain above the higher section, so that mechanical or chemical excitation of the cortex should cause no effect on the limbs. But Dr. Brown-Séquard asserts that under these circumstances not only does stimulation of the motor centres act energetically upon the limbs, but the same effect is produced by stimulation of parts which are not considered to be motor, such as the opto-striate bodies. In this case, also, the effect is usually most marked on the same side as that stimulated. An analysis which Dr. Brown-Séquard has made of five-hundred cases of unilateral convulsions in consequence of varied lesions of the brain, shows that the same result is true of man as of animals. Irritation of the base of the brain and the adjacent motor region causes convulsions more frequently on the side irritated than on the other. The superficial parts of the brain, it is true, produce chiefly crossed convulsions, but irritation in all parts *may* cause convulsion on the same side.

The conclusions drawn by Dr. Brown-Séquard are that one of the chief foundations for the theory of psycho-motor centres, and of the crossed functional relation between the hemispheres and the limbs, must be considered to have lost its value; and, secondly, that the excito-motor zone of the cerebral surface, and indeed all the excitable parts of the brain, are capable of putting in action the limbs of the same side, as well as those of the opposite side, and that they may produce these effects after the transverse division of one-half of the pons Varolii, of the medulla, or of the cervical cord, and even after two sections of the base, one of the right half and the other of the left, provided a certain interval exists between the two.—*Lancet*, June 10, 1882.

Heat-stroke.—From a careful study of the subject, M. H. Longuet draws the following conclusions: First, as regards the pathology of the affection, he believes that failure of the heart is the essential symptom, possibly due to coagulation of the myosin of the heart muscle from exaggerated external heat; associated with this there is asphyxia from loss of respiratory power of the blood corpuscles. Clinically it is difficult to differentiate between heat-stroke and sun-stroke, possibly the cerebral symptoms are more pronounced, and occur more frequently in sun-stroke. Suppression of perspiration constitutes a grave symptom. In treatment, cold baths and douches are recommended, and subcutaneous injections of quinine, pilocarpine, and ether.—*L' Union Médicale*, August 22, 1882.

Contusion of the Popliteal Artery without Damage of the External Parts, followed by Thrombosis and Death.—The following case is reported in the *France Médicale*. A man, thirty-two years of age, was run over by an omnibus and brought to the Hospital Necker. The wheels of the omnibus ran over the lower limbs just below the knee-joints. The right limb was seriously damaged, and there was a good deal of bleeding, which was stopped by a tampon. On the left limb there was a large ecchymosis, without any damage of the external parts. Both knee-joints were infiltrated and immovable. On the following night there was noticed considerable friction sound under the knee-joint, Both limbs were treated antiseptically. The pulse was 100; temperature 86°, and the patient vomited. The next day all the symptoms were aggravated; temperature 80°. The left limb was cold, insensible, and no arterial pulsations. The patient vomited severely. The next day gangrene of the left limb set in. Antiseptic treatment was abandoned on account of the dark-colored urine. An operation was not determined upon, on account of the severe general symptoms (*sic!*). The patient died after being five days in the hospital. The autopsy showed a bi-malleolar fracture of the right limb and bloody infiltration. On the left limb the lesions were highly interesting. The articulation of the knee-joint was filled with blood. The subcutaneous tissue was largely infiltrated with blood, and the infiltration was dispersed through the muscular interstices down to the foot. The soleus muscle was partly ruptured, and torn from its superior insertion. The popliteal artery was not ruptured. On the posterior aspect of the tibia, the popliteal artery appeared to be blackened, and cylindrical in form. The external wall of the artery was infiltrated with blood and there was a complete occlusion, the artery forming a flat cylinder. This was caused by a contusion of the artery, which had been pressed between the tibia and the wheels of the omnibus. On opening the artery there was a dark clot, three cm. long, adhering to the anterior walls of the vessel. The inner coats were ruptured, and the adventitia infiltrated with blood. The aorta, the femoral artery, and the sigmoid did not show any signs of atheroma.—*Chicago Medical Journal and Examiner*, August, 1882.

The Chemistry of Putrefaction.—The chemical mechanism of putrefaction, and the nature of the alkaloids which result, is the subject of a recent communication to the Paris Académie des Sciences by MM. Gautier and Etard. They had previously shown that, as soon as the putrid fermentation of albuminous substances is well established, the reaction becomes alkaline, hydrogen disappears, and carbonic acid is released, at first rapidly, afterwards more slowly, mixed with a little nitrogen and with traces of phosphuretted and sulphuretted hydrogen. At the same time, the liquids contain ammonia, with a little trimethylamine, fatty acids, lactic acid, a small amount of oxalic acid, traces ef tyrosine, phenol, scatol, indol, guanidine, xanthine, and organic alkaloids. These substances are accompanied at the commencement by a mass of glucoproteins and a soluble proteoid substance, which disappears slowly. The authors of the paper believe that all this complex series of substances is due to the circumstance that the putrid fermentation breaks up the albuminoid molecule by a method of simple hydration, and reveals its complex constituents. The process really resembles the hydration of the albuminoids by baryta, which has been studied by Schützenberger, in which there is a similar liberation of ammonia and of carbonic acid, and of a like series of substances. Thus the albuminoid molecule is doubled under the influence of bacteria, just as under the influence of water aided by heat and alkalies; and it breaks up into two principal parts: one relatively resistant, from which the glucoproteins and later the leucines are derived; another unstable, forming ammonia and carbonic and other acids. It is supposed, therefore, that the odoriferous bodies observed during putrefaction, and also certain bases which may be obtained, must pre-exist in what is termed a "nuclear" form in the albuminoid molecule. To extract the basic substances the following method was found to answer best. The liquid products of putrefaction were acidulated with sulphuric acid and evaporated in vacuo, by which means the volatile acids, indol, phenol, etc., escaped. The residue was rendered alkaline by the addition of baryta, and then filtered and shaken up with chloroform, which dissolved the bases. They were extracted by fractional distillation of the chloroform and treated with tartaric acid. Potash added in excess to the tartaric solutions liberated a strong odor of carbylamine, and set free the oily bases, which could be separated by ether and dried in a vacuum. These resembled the bases described by Selmi: oily colorless liquids, bluing litmus, neutraliz-

ing strong acids, and giving with nitric and hydrochloric acids, ferrocyanide of potassium, and ferric salts, the reactions of ptomaines. They were precipitated by bromine, iodine, and the phosphomolybdates. They quickly became resinous.—*Lancet*, July 22, 1882.

CASE OF EXTIRPATION OF THE LARYNX.—At a recent meeting of the Würzburg Medical Society, PROF. BERGMANN presented a patient in whom he had performed extirpation of the larynx. The following is an abstract of the history of the case: The patient was a man aged 54, always in good health until the summer of 1880, when he began to suffer from hoarseness and dysphagia, and laryngoscopic examination made October, 1881, revealed the following conditions: The epiglottis was normal; on the left ary-epiglottic fold there was a large warty tumor; the left true and false vocal cords were fused together; the cavity of the larynx was greatly contracted, and the true and false vocal cords on the right side were thickened, reddened, and ulcerated. The restricted character of the disease led the author to hope for improvement under local treatment, but the laryngeal stenosis increased to such an extent that tracheotomy had to be performed on December 6th. Extirpation of the larynx was performed on January 16th. Prof. Bergmann found that the previous performance of tracheotomy was no advantage and indeed rather interferred with the operation: he therefore advises the non-performance of tracheotomy until after the thyroid cartilages have been cleared. And from the difficulty of dissecting off the constrictor of the pharynx, there is always a danger of getting into the space between the œsophagus and spinal column: he advises the division of the thyro-hyoid ligament, the seizing of the laryngeal artery with forceps, and the rapid separation of the larynx from the pharynx. The larynx is excised immediately below the cricoid cartilage, the first tracheal ring being previously fastened to the skin. The wound was treated with iodoform and corrosive sublimate gauze: three deep stitches were passed through the skin, to which the posterior wall of the trachea was fastened, and stitches were also passed through the mucous membrane of the pharynx. Healing took place without febrile reaction. The patient now wears a Brun's canula with which he is able to speak in a loud, clear voice.—*Deutsche Med. Woch.*, August 26, 1882.

RECOVERY FROM TRAUMATIC TETANUS.—At a late meeting of the Cambridge Medical Society, MR. SHIELD related the case of a lad who had recently been treated in the hospital for tetanus, and recovered, as follows: A healthy country lad, aged seventeen, was admitted on May 30. He was suffering from an extensive lacerated, contused wound on the flexor aspect of the left forearm, the result of the explosion of a gun. From June 23 to July 12 the symptoms were very severe, marked opisthotonos was observed, and the patient got rather emaciated. On July 10, the twenty-third day of the disease, it was on the wane. Gradually the spasms grew less severe, the bowels acted naturally, and the appetite improved, while the patient was walking about the ward, with his wound nearly healed, and all tetanic symptoms were gone. Throughout the whole case the temperature was, for the most part, above normal, presenting curious diurnal variations, while on several occasions it reached the height of 104° to 105°. The pulse was quick and weak, and varied slightly with the temperature. The tonic spasmodic condition of the muscles did not relax during sleep; and muscles of the eyeball and tongue were not affected. The superficial muscles were extensively disintegrated, the radial artery was torn away, but the main nerves had escaped injury, and the ulnar artery was intact. The wound was treated by poultices and carbolized oil, and all went well until June 17, when symptoms of tetanus set in, with slight stiffness about the muscles of the jaws and of the neck. On June 19 these symptoms had become more pronounced, well-marked trismus was present, with epigastric pain. By June 23 the disease was fully developed; severe spasms, especially of the muscles of the back, were constantly present, the tongue was foul, the breath offensive, the bowels were constipated, and the pulse quick, while the temperature was high and the urine scanty and high-colored. Excessive sweating was also present, so that an eczematous condition of the cutaneous surface was produced. The onset of the disease, therefore, occupied about five days. The treatment adopted depended chiefly upon feeding and nursing. Plenty of good milk and eggs, with port wine and brandy, were frequently administered both by day and night, and fortunately swallowed and retained by the patient. Hypodermic injections of morphia were administered every evening, when the anguish was severe, and caused relief and some snatches of sleep. The bowels were relieved by enemata, and during their peristaltic action the patient seemed to have his sufferings increased, but after the evacuation the pains were alleviated. He smoked tobacco twice, and this gave him some relief from the accumulation of mucus in the fauces.

PROF. HUMPHRY had seen a great many cases of tetanus, and had arrived at certain conclusions respecting it. First, that it is a passing malady depending, probably, like small-pox, scarlet fever, and others, upon some blood-poisoning; like them, being amenable to no known curative treatment, but running a certain course and subsiding, provided it did not kill the patient in its course; that, like them, it is fatal in proportion to the acuteness and severity of its onset. Of the rapidly progressing cases very few survive, whereas in those which come on more tardily, and more particularly in those in which the patient continues to be able to take food, a favorable result may, by good management, not unfrequently be obtained. Secondly, that the disease is attended with much wasting and exhaustion, sometimes with high temperature, and that the most important feature in treatment is to give nourishment, which must generally be in a fluid form—milk, eggs, beef-tea, wine, etc.—as much as the patient can take. While food can be swallowed there is hope. It must be urged upon the patient, who is often reluctant to take it; and no other treatment should be allowed to interfere with this. Sedatives, such as morphia, hypodemically injected, tobacco, and others, come in as adjuncts in the more severe cases, but are better abstained from unless the case is severe; and reliance should be placed solely on the feeding, with attention to the bowels, it being commonly necessary to give aperients. The worst case he had known to recover was that of an infant in whom the removal of a considerable tumor from the back of the neck was followed by tetanus. The spasms were so frequent and so severe that on several occasions the child was thought to be dead; and in this case, as in others he had observed, the seizures were most severe after a very prolonged interval, as after sleep. Still the child swallowed milk. The milk was sedulously given, no other treatment being allowed, except subjecting the child to the fumes of tobacco smoked by persons near it, which was thought to do some good; and in other cases he had found tobacco, smoked or administered in a mild form, to have a soothing effect. He had kept patients persistently under the influence of chloroform, without any benefit. The maintenance of strength by nourishment, so as to enable the patient to tide over the attack, is the great thing to be aimed at. —*Med. Times and Gazette*, Sept. 2, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, SEPTEMBER 23, 1882.

PRE-HISTORIC SYPHILIS IN EUROPE.

THE interesting question as to the antiquity of syphilis which has for many years been discussed intermittently in medical societies and journals, and which seems to have lost none of its historic, or rather its archæological, interest, has recently received two valuable contributions. In the *Annales de Dermatologie*, for January and February of this year, M. Rollet very learnedly reviewed the subject, and showed how it is proved by the documents of the priests in India, by the records of voyagers in China, of explorers in Africa, and of historians and discoverers in America, that syphilis existed in all these countries from the remotest periods. In Europe alone, according to M. Rollet, of all the countries of the world of which we have any definite knowledge, did syphilis remain unknown up to comparatively modern times—the end of the fifteenth century—and he adds that investigations among fossil remains and in old cemeteries only serve still further to establish this fact, by the absence of any syphilitic lesions upon the bones thus exhumed. The one exception which has hitherto been quoted in opposition to this was the discovery of syphilitic exostoses upon the right tibia of a female skeleton, disinterred at the Solutré. These have been described by Broca, Ollier, Parrot, and Virchow, but their value as evidence in regard to the date of appearance of syphilis was destroyed by the Abbé Ducrost, to whom their discovery was due, but who raised grave doubts as to the antiquity of the sepulchre.

In the *Revue Scientifique*, for July 22d, M. Parrot takes up the subject in an interesting paper, describing, first, the characteristic appearances of cranial and dental syphilis, then those of three American skulls obtained from ancient cemeteries, and finally, with much minutiæ, the teeth and maxillæ of a young person from a place of burial belonging to the Merovingian epoch, antecedent to the seventh century, and others with pieces of the cranium from excavations in the caverns of Lozere, and elsewhere, and undoubtedly of pre-historic date.

The well-known appearances of hereditary osseous syphilis were here unmistakably present. Upon the external face of one of the fragments—a portion of a parietal bone—there was a layer of new bony tissue, hard, porous, with a rounded border terminating abruptly at the healthy bone, made up of trabeculæ, perpendicular to the surface beneath; in other words, having the characteristics of the osteophytes which are seen daily upon the skulls of children attacked with hereditary syphilis. In other specimens similar growths were observed, and several of the incisor teeth presented the unmistakable notching and grooving which belong only to syphilis. M. Parrot seems to have well established the antiquity of his specimens, giving his authority and the place of disinterment in each case. His usual accuracy of observation and his large experience in such cases are well known, and the appearances he describes are beyond all doubt those of syphilis. If all these facts remain undisputed, it is the most conclusive contribution to the literature of the subject which has yet been made. The existence of very ancient syphilis in America has long ago been demonstrated. The writer has seen ten years ago, at this very cemetery near Callao, from which one of M. Parrot's American specimens was taken, and which seems to be inexhaustible, a number of skulls showing evidences of syphilis. Dr. Jones, of New Orleans, has proved its presence among the mound-builders of North America. Numerous facts, as we have stated, establish its existence in most of the countries of Asia and Africa, but this seems to be the first clear demonstration of its prehistoric existence in Europe. We shall look with interest for corroborative evidence upon the subject.

THE MEDICAL PROFESSION AND ITS MORALITY.

The *Modern Review*, an English publication rarely seen in this country, lately had an article with the above title, in which Miss Cobbe, "a ruthless critic" indeed, makes a most outrageous and untruthful attack on the profession. In succeeding numbers of the *Review* Dr. Wm. B. Carpenter and "two members of the profession," and finally Dr. Blackwell, make replies, which, in their facts, are ample; but we must confess that as to style the assailant has a

vigorous English at command that is wanting in the defence. True it amounts almost to fretful vituperation such as Gail Hamilton uses in her "Spent Bullet," but it has all the stiletto-like thrusts, the epigrammatic style that characterize Miss Dodge's nervous English.

The animus of the authoress is especially shown by the cant as to vivisection, vaccination, the Contagious Diseases Acts, and the attempted exclusion of women from the profession. All the venom that can be put into language is used in discussing these questions.

We are told that this dreadful profession is meddling, despotic, arrogant, and with the aid of a bullying medical press they are even dictating to parliament. They are "Modern Inquisitors," a "parvenu profession with the merits and demerits of the class."

Both authoress and editor endeavor to make it appear that the charges are not against the profession as a whole, but only some members of it. If anybody can draw any other inference than that the authoress means the great bulk of the 45,000 doctors of Britain, with comparatively few exceptions, we mistake the impressions produced by ordinary language. True, she is expressly indignant at the fashionable doctors of the great cities and of the health resorts, but her denunciations are too sweeping to apply to them alone. So, too, she excludes the greater crimes, murder, seduction, etc., but with such damning "if's" and "but's" that every doctor feels she smirches him by her touch.

The cruel slanders that the doctors' kindness is merely a part of their "stock in trade," that they spread a trail of cold and slimy doubt in their track, and the dark hint that their facilities for concealing crime are equal to those for committing it, so far transgress the daily experience of every one in the community, that we dismiss them as unworthy even of an attempt at refutation.

But what are the charges? They are five in number. First, that in our scientific enthusiasm we forget the patient and study the disease instead of curing it. She abhors the doctor who would "study patients to acquire science," but honors the physician who "studies science in order to cure his patients." The Lord help such logic! As if science, which is to be studied in order to cure patients, were not the result of previous study of the patients.

But, not only do the doctors experiment upon their patients in hospitals and even in private practice, but they add to the bodily anguish the "moral tortures of outraged modesty," lest Mr. Bob Sawyer and his ilk be disappointed. Moreover, both to keep their hands well "in," as well as to exact enormous fees, the surgeons operate needlessly, and she tells a pathetic story of a pair of most beautiful eyes in a handsome head preserved by a refusal to be "relieved of one splendid orb," and pay $400 for the loss. We leave such logic again with uplifted hands, for more serious charges lie beyond.

Secondly, the pecuniary interests of the patient are sacrificed to those of the profession. As evidences she points to the semi-charlatan recommendations of waters and wines and such rubbish; to the new remedies, which are "costly fads of medicine," and are as changeable as the fashions; to the reckless multiplication of expensive prescriptions and incidentally hints at an "*entente cordiale* between the doctor and the druggist." Most of these have really some food for thought. But the next point is even a more serious one. "How far do medical men generally, really, and honestly strive to cure their well-paying patients?" she asks. Of positive evidence she admits there is none, but again she uses damning "presumptions," and intimates a strong belief that at least the rich are kept ill and made to pay well for the luxury. Suppose a specific for gout, neuralgia, or dyspepsia were found, what welcome, she asks, would it receive from the medical profession? In answer we point to quinia in ague, to the iodide of potash and mercury in syphilis, and to her despised and abhorred vaccination in small-pox. She points out, it is true, that in thirty years the doctors have received for vaccinations some $8,000,000 from the "rates" independently of private fees, and thus accounts for the "zealotry and cruelty wherewith this medical 'rite' is upheld." But we would ask in return what would have been the fees if small-pox had been let loose upon the community? Not less than $50,000,000, and perhaps far beyond even that large sum.

But thirdly, we are a trades-union. Consultations are a mere formality or rather a "solemn farce," and when the farce is ended Dr. A., after eating an excellent luncheon in the house of mourning, pockets his magnificent fee, rides in luxury to the station, and reads on his way up to town a charming article on the intense sympathy of medical men. He "has told a shameful and cruel lie, and has taken money from the very victim of his falsehood." We ask with confidence her own question: "Let us, for heaven's sake, know where we stand. Will the doctors tell us the truth beside the sick-beds of our friends, or will they *not?*" and we answer unhesitatingly *they will and they do.*

The fling at coroners who may aid in covering up crimes committed by medical men is so little applicable in this country, and we believe is so utterly untrue in England, that it is not worth our consideration.

The fourth charge that the profession has been doubly treacherous to women in passing the Contagious Diseases Acts, and in endeavoring to exclude

them from the profession, is so trite a subject that we need not say a word about it.

Lastly, the profession is so aggressive, that give them a chance, and in two-score years or so the doctor will lord it over "birth, marriage, education, employment, sickness, and death," and on the heels of his certificate, attendance or sanction, a large fee will follow of course—in short, personal liberty will be gone and the community will be reduced to two classes—doctors and their helots.

The editor says at the close of the article: "It is not without a grave sense of responsibility that we publish the above article," on the ground forsooth that the clergy and the lawyers have been criticised, but the doctors have escaped it (?!).

Besides the erroneousness of this contrast, we submit that the article as we have outlined it is not criticism, but calumny. Fair criticism we invite. Calumny we must and we do protest against and repel, both for our English brethren and ourselves.

PERFORATION OF THE BOWEL AND ITS TREATMENT.

WE have lately alluded to the proper surgical treatment of perityphlitis; of gunshot wounds of the abdomen, and also to the general question of the more radical *versus* the more conservative surgery of the abdomen. Allied to these topics is the question of the treatment of perforations of the bowel either in typhoid fever; from ulceration caused by foreign bodies in the cæcum or the appendix vermiformis; by fecal abscesses in the left groin, and other similar conditions. The tendency of the present day in the surgery of the extremities, on the one hand, is justly growing more conservative, as resections and osteotomies, mechanical treatment, and other similar procedures amply attest; but, on the other hand—and this tendency is unquestionably the right one—it is more and more towards radical treatment in the surgery of the abdomen, especially since our methods have so far improved as to make laparotomy one of the more successful instead of one of the most dangerous operations.

In the case in hand, where perforation has occurred, with escape of the contents of the bowel into the peritoneal cavity, what may we reasonably—nay, certainly—expect? Peritonitis, collapse, death, in from a few hours to a few days. Look at the forty-seven cases collected by Lewis in 1856 of abscess of the appendix vermiformis usually followed by perforation. Forty-six deaths! one recovery! Could any operation have been followed by a higher mortality?

In typhoid fever it may often be a question whether it is advisable to do any operation in view of the general condition of the patient. But even here an operation might sometimes be justifiable. But in cases of perforation of the appendix, or of ulceration of the bowel—supposing that it may be ascertained with reasonable certainty—we believe that the abdomen should be opened, the matters that have escaped be removed as thoroughly as possible, the opening sewed up by a "purse-string suture," or otherwise according to circumstances, and that the patient will thus have a better, a far better, chance of recovery than if he be let alone. The latter course has but one termination; the former has a possibility, though a poor one, of two. Lewis asked the question in '56. We are just beginning to consider the answer after the lapse of a quarter of a century.

INHIBITION AND DYNAMOGENY.

WE owe these new observations on the nervous functions to Brown-Séquard. The terms will now be so largely employed that our readers, we doubt not, will be pleased to have some information about them.

By *inhibition* is meant an action by which an activity or a function is, suddenly or nearly suddenly, suspended and apparently annihilated.

The inhibitory faculty or property appertains to a great number of parts of the nervous system, and may be put in action in a direct or reflex manner. All of the activities, all of the normal or morbid properties of the central or peripheric nervous system, and consequently all the functions of this system may, perhaps, be inhibited. The irritability of contractile tissues may also be inhibited.

That which is true of inhibition is also true of *dynamogeny*, which means the power to make potential energy actual. Thus, to take an illustration from Brown-Séquard's experiments, irritation of a certain area of the skin, on the face usually, will cause an epileptiform seizure in those guinea pigs affected with the artificial malady. Such an area is *dynamogenic*, in that it possesses the power to so irritate the spasm centre as to make the potential energy there stored up take on an active phase.

The dynamogeny which is due to irritations of the skin, and of some parts of the nervous system in animals, may be made to attain a degree of activity six to ten times that of the normal state. In man the tactile sense may become dynamogenic to such a degree that the points of the æsthesiometer may be perceived on the back at a distance one hundred times less than the ordinary distance.

Inhibition and dynamogeny are in general produced simultaneously by the same irritation. The pretended motor centres in the encephalon may be inhibited or dynamogenic as other parts of the nervous system. The increase of strength of the spinal cord as a motor centre, and of other parts of the nervous system which contribute to the muscular sense, may attain to an enormous degree.

The phenomena of increase and diminution of force, the properties exhibited in Braidism and hypnotism, and the transfer of anæsthesia, also pertain to inhibition and dynamogeny.

THE TREATMENT OF CONSUMPTION BY ELECTRICITY.

ALTHOUGH not a new expedient, nor a novel application of an old one, Dr. Alavoine's method and its results deserve attention as additional proof of the efficacy of treatment which has, hitherto, attracted but little attention. He employs an induction current, and by means of it excites in turn the nerves engaged in the respiratory acts. He, also, stimulates the pneumogastric nerve, and thus lessens the action of the heart, and consequently diminishes pulmonary congestion. He applies a small olive-shaped metal electrode in the fossa behind the angle of the lower jaw, and a corresponding one over the pneumogastric near the sterno-clavicular articulation. Commencing with feeble currents, he continues the applications, slightly increasing their strength, for a quarter to a half hour. The immediate effect is a dilatation of the lungs, an increase in the depth and amplitude of the respiratory movements, and a diminution in their number. The expectoration is at first notably increased, after a while it lessens, and ultimately almost ceases, unless there is very extensive softening and destruction of the pulmonary tissue. At the same time the fever lessens, the respirations become more easy and deep, the condition of the blood improves, sleep is free from dyspnœa, nocturnal sweats disappear, the appetite returns, and the process of repair begins.

PROF. WHITTAKER'S LECTURE ON THE BACILLUS TUBERCULOSIS.

OUR readers have been more than usually delighted with the charming letters of J. T. W., our correspondent on the Continent, relating chiefly to Koch's recent discovery of the alleged bacillus of tuberculosis. Prof. Whittaker—of whom our Cincinnati friends may well be proud—reached this country a few days ago, and on last Monday, at the invitation of the College of Physicians of Philadelphia, he delivered a lecture on Koch's discovery, at the Hall of the College, before a large and interested audience consisting, to a great extent, of leading men of the profession. Dr. Whittaker not only gave in some detail Koch's methods, but also placed under five microscopes several slides illustrating the results—especially the bacillus of milz-brand, of perlsucht, and of tuberculosis. The lecture was admirably given, and our readers who did not have the rare treat of a personal hearing, will have the pleasure of perusing its substance in our columns next week.

The unanimous "aye" which responded to Prof. S. D. Gross's motion for a hearty vote of thanks, was but the expression of the feelings of all present.

THE NAVAL MUSEUM OF HYGIENE.

SURGEON-GENERAL WALES, of the Navy, has organized a "Museum of Hygiene," which has, it appears, been made the "permanent central repository" of the American Public Health Association. Singularly enough, in a museum of hygiene under the control of a naval bureau, we find almost no provision for naval hygiene. One of the classes (19) is water transportation, one (39) marine architecture, and one (37) hospital ships, but these do not embrace the great and important subject of the health of seamen. Soils, sewage, water-supply of towns, factories, hotels, etc., are subjects to which the museum is to be devoted, and many others equally foreign to the naval service. The museum of hygiene is commendable enough, but, surely, it ought to have a special direction, since Congress has authorized its establishment by the Bureau of Medicine and Surgery of the Navy. If a repository of the Public Health Association, it should, also, illustrate all the conditions of naval hygiene.

THE EASY PREPARATION OF CATGUT LIGATURES.

WHETHER one pins one's faith to the antiseptic system or not, the use of catgut ligatures is so important and so general that we call attention anew to the simple and easy method of preparation which Mr. Lister introduced and published last year. Any doctor can prepare them for himself within a couple of days, and keep them constantly on hand.

Add one part of chromic acid and 200 parts of carbolic acid to 4000 parts of water. To this mixture (as it undergoes change in a short time) add immediately 200 parts of catgut of suitable thickness. After soaking for forty-eight hours, dry the catgut and place it in a mixture of carbolic acid and sweet oil, a drachm and a half to the ounce (1 to 5), in which it may be kept indefinitely.

RELATION OF ATOMIC WEIGHT TO TOXIC ACTIVITY.

RICHET has conducted an elaborate research on the metals of the alkalies, to determine whether there is a relation, as has been supposed, between the atomic weight and the toxic power.

To determine with precision the lethal dose, Richet employed the same species of animal, administered the quantity with regard to the weight of the animal, and injected the solution under the skin and not into the blood. He found that in the series of alkaline metals there was no relation between the atomic weight of the metals and their physiological activity. Thus rubidium, which has a high atomic weight (80), is much less active than sodium, which is much lower (23).

SOCIETY PROCEEDINGS.

CANADA MEDICAL ASSOCIATION.

Fifteenth Annual Meeting, held at Toronto, September 6, 7, and 8, 1882.

(Specially reported for THE MEDICAL NEWS.)

THE Fifteenth Annual Meeting of this Association was opened in the City Hall, Toronto, on Sept. 6th, under the presidency of PROF. FENWICK, of Montreal.

The Chairman of the Committee of Arrangements, DR. CANNIFF, welcomed the Association to the city, and announced that the programme which had been made out was ready for distribution.

The minutes of the previous meeting were read by the General Secretary, DR. OSLER.

Dr. Elsberg, of New York; Dr. Walker, of Detroit; Dr. Goodwillie, of New York; Dr. Lough, of Bermuda; and Dr. Field, of Barbadoes, were elected members by invitation. Dr. Brodie, of Detroit, was present as delegate from the American Medical Association. The

REPORTS OF THE VARIOUS COMMITTEES

were then taken up. On *Necrology*, by DR. FULTON, who presented a list of the members who had gone to their last resting-place since the previous meeting. On *Medicine*, by DR. GRAHAM. The chief topics touched upon were the International Medical Congress and its results, and the discovery by Dr. Koch of the bacillus of tuberculosis. At this point

DR. W. B. CARPENTER, OF LONDON,

entered and was enthusiastically received. On the motion of DR. ADAM WRIGHT, he was elected an honorary member.

At the request of the President, DR. CARPENTER addressed the meeting on the subject of

ZYMOTIC DISEASES AND VITAL STATISTICS.

The following is an abstract of his remarks: He emphasized the advantages of a strictly uniform system of taking statistics, such as prevailed in Great Britain. The system of tabulating had been inaugurated by Dr. Farr, to whom they owed much in connection with this subject. He paid a high tribute to the labors of this gentleman. Sir John Pringle's treatise he regarded also as of very great value, and one of the earliest to call attention to the group of zymotic diseases. Sir John had been connected with the army, and wrote a book on diseases of the army, and also a treatise on fermentation. The speaker then referred to the possibility of the transmutation of certain of these affections. Some examples were given. At the conclusion of the rebellion of 1745 a number of the troops were shipped off in little brigs. Some of the men were suffering under the mild autumnal fever. The brigs knocked about for six weeks, and for part of the time the men were enclosed under hatches without ventilation. In consequence of the unsanitary conditions the fever changed by the process above referred to into a malignant typhus. They landed, and the disease spread among the villages in which the men located. Another instance had come under his observation of the malarious fever of the west coast of Africa changing under similar conditions into yellow fever of a contagious character. The men suffering from a milder fever had been brought under the influence of bilge water in the vessels, and the result was the transmutation of the mild fever into malignant yellow fever. Dr. McWilliam and others had reported similar cases of convertibility of these kinds of fever. No general doctrine, he said, could be right that did not take into account these cases of transmutation, because the evidence of such cases was beyond dispute. When he was in Edinburgh he had a conversation with Sir Robert Christison, whose clinical clerk he had been forty-five years ago, and that gentleman had expressed the opinion that no distinct line could be drawn between certain kinds of fever. In his practice in Edinburgh Sir Robert had found cases of variation and transmutation of the nature he had been referring to. Before ever Darwin's views were laid before the world, and quite apart from theory, he (Dr. Carpenter) and other medical gentlemen with whom he had discussed the subject had held decided opinions regarding the variation and convertibility of disease. The medium in which germs are developed had been found to alter, in a very great degree the nature of the disease resulting. For example, when the germs were developed in a subject predisposed in any way, the nature of the disease was very different from that produced from the same germs in a subject not so predisposed.

The rate of mortality from non-zymotic diseases was practically the same in town and country and in towns of different characters. The annual mortality from zymotic diseases in London, with a population, taking in Croyden and the whole metropolitan area, of about 5,000,000, was not more than 15 or 16 in the thousand. In other cities and towns the rate was much higher, arising from the fact that in these latter places sanitary reforms and means of preventing disease from transmutation into malignant type were not properly attended to. In a certain place of industry fine-looking houses were built on a foundation of chalk, and the sanitary condition of the locality was brought before the Board of Health. The chalk had become saturated, and the Board recommended thorough drainage. A dispute arose. The place was divided into a clean and dirty party. The latter party prevailed, and drainage was deferred. The consequence was an outbreak of cholera of the most malignant type, which he had no doubt would have been prevented by proper means. He was of opinion that the late illness of the Prince of Wales had done a great deal to introduce sanitary reform in England. Vital statistics proved of the utmost importance in showing the causes and conditions of these malignant outbreaks and the conversion of mild into severe types of disease.

Dr. Carpenter next spoke on the subject of smallpox. During late years he had had occasion to fight the opinions of anti-vaccinators. The recent outbreak of smallpox on the continent of Europe was of a singular character. It had not before been epidemic since the middle of the last century. Since 1871 in London the mortality of the non-vaccinated had risen as high as 45 or more per cent. In the year 1612 the old form of black smallpox had devastated the whole of Europe, and the mortality had been as great as in the case of the plague—in many cases death occurred before the eruption came out, the patients dying from hemorrhage under the skin and in the bowels. Against this malignant type inoculation of a milder type had been successfully tried as a means of protection. As to the origin of this malignant type, he had not the least doubt it arose from overcrowding of the soldiers in the French military habitations. It was proved beyond doubt that thorough vaccination and proper sanitary measures were the best possible protection against a malignant type of smallpox. No child properly vaccinated had ever been afflicted with anything but a mild type.

A matter of great importance was the using of proper vaccine virus. There was no doubt it became eventually deteriorated by transmission through the human body, and the results were not always satisfactory. When properly cultivated and taken directly from the cow the effect was quite different. When the

great epidemic visited San Francisco the public seemed thoroughly frightened. The municipal authorities enacted that all the school children should be vaccinated. This was done with good results, and notwithstanding the unfavorable habits of the Chinese in the course of a few weeks, by isolation and vaccination, the epidemic had been brought under control.

In the Baltimore poorhouse in 1849 he had heard of a remarkable result of the adoption of proper sanitary measures. The site of the poorhouse had been selected for its salubrity. When the cholera prevailed all around, there were very few cases in Baltimore. But strange to say there was a great outbreak in the poorhouse. Forty or fifty cases occurred every day, and many were fatal. The Board was summoned in great haste, and there was something approaching a panic. One member, more sagacious than the rest, examined behind one of the walls, and found a rank marsh overgrown with grass. Into this marsh all the excreta was drained. All those located on the side next the marsh became ill first, and the mortality was great. The marsh was immediately drained, scoured, and covered with lime. The next day there were very few fresh cases, and on the third day there were none at all. At a meeting of clergymen he had expressed the opinion that in former times an epidemic of this kind was regarded as a visitation of some deity. Such a case as that referred to, was no doubt an infraction of law, but would a remedy have been effected if all the people of Baltimore had gone down on their knees for a week? To the medical profession these remedies were entirely due, nothwithstanding that they were in introducing these preventive measures, acting directly against their own interests.

DR. SWEETLAND, of Ottawa, moved a vote of thanks to Dr. Carpenter for the very able address he had delivered. He thought the remarks of Dr. Carpenter should be put into effect, by pressing upon the Government the establishment of a bureau of statistics for the proper registration of zymotic and non-zymotic diseases, so that proper sanitary steps might be taken in cases where such steps might be considered likely to be of advantage.

The vote of thanks was seconded by DR. OLDRIGHT, and very heartily acquiesced in by the members present.

DR. OLDRIGHT desired to know what was done in the matter of health statistics in Britain, the connection of wells and sewage, and the isolation of contagious diseases.

DR. PLAYTER suggested that the matter be delayed, as the time at present was too short to enter into the subject.

A number of new members were elected, and the meeting adjourned to meet at 4 P.M. in sections.

The afternoon and evening sessions were devoted to work in Medical and Surgical Sections.

AFTERNOON SESSION.—MEDICAL SECTION.

DR. MCDONALD, of Hamilton, *Chairman*. Dr. STEWART, of Brucefield, Ont., *Secretary*.

ECHINOCOCCUS DISEASE IN AMERICA.

DR. OSLER communicated the results of an inquiry into the prevalence of the affection on this continent, and stated that he had been able to collect from the journals and private sources 61 instances. Drs. Temple and Graham each narrated a case.

AXIS TRACTION AND TARNIER'S FORCEPS.

DR. CAMERON, of Montreal, read an elaborate paper on this subject, illustrated by diagrams, etc. The head followed the axis, and the problem to be solved was the best means of assisting nature. Some advocated traction, some leverage, some compression, others a judicious combination. He exhibited different specimens of the forceps, and explained the difference between the *vis a tergo* exerted by nature and the *vis a fronte* of the forceps. There were three kinds of forceps, the straight, the pelvic curved, and the curved with detractors of Tarnier. The advantage of the straight forceps was that they did not interfere with the natural rotation of the head, but a great disadvantage was that when the head was high up the instrument could not fail to come in contact with the coccyx. There was also the liability to slip and injure the perineum and soft parts. The curved forceps were less liable to slip, but the line of traction was not in the axis of the pelvis, and if the instrument was so adjusted as to bring the line of traction right, it would be sure to come in contact either with symphysis pubis or the sacrum. To combine the advantages of these two kinds of instruments and eliminate their disadvantages, Tarnier had invented his double detractor, which had the advantage of action along the traction axis and at the same time permitting the natural rotation of head. The objections urged against Tarnier's instrument was its clumsiness and cost and the danger of injuring the internal cavity.

DR. HOLMES, Chatham, said he had been accustomed to use the forceps in the manner recommended by Dr. Albert Smith, both as a lever and as a detractor. He also found it advantageous to advise the woman to abstain from direct pressure, and he had thus been enabled to avoid laceration.

DR. TEMPLE remarked that he was not prepared to concede all said in favor of Tarnier's forceps; they have not had sufficient use for their universal adoption in all cases; they are expensive, cumbersome, complicated and difficult to keep clean; the only advantage he thought they have over the double curved long forceps is in posterior occipital positions; in this position their traction is very similar to the long straight forceps, which are much more easy of application in this position than the curved forceps and less liable to slip. He was much in favor of simplicity in obstetric forceps.

DR. STEWART, of Brucefield, could not see the advantage of Tarnier's forceps over the older forms. He had seen in Vienna cases of rupture of the vagina and death after the use of this instrument.

THE USE OF THE UTERINE SCOOP IN INEVITABLE ABORTION.

DR. ALLOWAY, of Montreal, gave his experience of the use of this instrument in 20 cases. He strongly recommended its use instead of the placental forceps. He criticised at length certain of the views on the treatment of abortion.

DR. TYE, of Chatham, said he really thought they were passing through the iron age in the matter of obstetrics. After seeing all the forceps and scoops and other iron instruments, he really congratulated himself that he was not a woman. In his practice he relied chiefly on the instruments provided by nature, and he found them very suitable.

DR. RODGER, of Montreal, while he disapproved of undue multiplicity and complication of instruments, yet thought that the valuable assistance rendered by them could not be overlooked. He spoke in favor of the tampon and placental forceps in abortion. After their use, and twenty-four hours' plugging of the os, matters were found in a satisfactory condition.

EVENING SESSION.

At the opening of the evening session, the PRESIDENT delivered

THE ANNUAL ADDRESS.

He thanked the Association for the high honor they had done him by electing him to preside. He referred

to the importance of the Association and the important and responsible position held by the honorable medical practitioner. He explained the mode adopted by the Association for the transaction of business and the spirit in which the work of the different sections should be carried on. It was an important matter to meet together and compare notes on matters relating to their profession. He spoke of the important functions performed by the British Medical Association, and said they might look to that Association for an example of what the Canadian Association might be, and the important work within its scope. He traced the history of the Medical Association, and gave it as his opinion that they might have been celebrating their jubilee, as the British Association was now doing, had it not been for the disagreement which at one time marked the proceedings of the Association and interrupted its existence. He hoped harmony would now exist, and that the work of the Association would ameliorate the status of the profession in Canada. He dwelt at some length on the subject of sanitary legislation, which was now so much attended to in Britian. He hoped the same attention would soon be devoted to the subject at Ottawa. The sum of $10,000 had been placed at the disposal of the Minister of Agriculture for the collection of statistics. But unless the matter received the approval and support of the medical profession throughout the Dominion this sum would do little towards obtaining reliable information. He thought operations of collecting statistics should be limited at the outset to certain cities to prevent failure, and a committee should confer with the authorities at Ottawa. The committee appointed at the last meeting should be desired to continue their work.

SURGICAL SECTION.

DR. GRANT, of Ottawa, *Chairman*. DR. ROSS, JR., of Toronto, *Secretary*.

SPASMODIC TORTICOLLIS.

DR. RODDICK, of Montreal, exhibited a patient who had suffered for many months with a very painful spasmodic contraction of the muscles of one side of the neck. The man was obliged to hold his head in his hands if he wished to keep it steady, and this was only temporary. Electricity and many other remedies were tried in vain, and Dr. Roddick divided some of the muscles subcutaneously with but little benefit. The actual cautery was applied on several occasions to the back of the neck with the most satisfactory result. The man recovered completely.

REST AND TRACHEOTOMY.

DR. MAJOR, of Montreal, advocated rest in all diseases of the throat, and rather denied the harm sometimes attributed to over-rest, claiming that (unless under tracheotomy) perfect rest was not attainable in the larynx, as the function of respiration had to be carried on even if that of phonation were suppressed. He reported results in cancerous disease of larynx and laryngo-pharynx, and held that the rest secured by operative or other means certainly controlled development, diminished the suffering, and prolonged life. He placed on record certain glandular enlargements under the sterno-mastoid muscle as an early means of diagnosis in malignant disease of the larynx, and gave in support his experience of seven cases, also attesting to the absence of these glandular enlargements in chancroidal, syphilitic, or other disease of this organ. He also upheld rest in warty growths and in tuberculous disease, and reported a number of cases having direct bearing on this point. He recommended a gold canula, as his experience with this metal justified him in doing so—it was less liable to irritate, and was not so easily acted upon by the secretions as silver; his notice was first attracted to gold as a substitute for silver, on finding that a gold plate which had lain in the trachea at its bifurcation for 113 days had not been acted upon. Gargles received a very warm denouncement, as a flagrant violation of the principle of rest was necessitated by their use. Dr. Major also explained the mechanical principle of gargling, and conclusively showed its uselessness as a means to the end for which it was intended.

DR. RYERSON entirely agreed with Dr. Major in regard to the value of rest in laryngeal troubles.

DR. ELSBERG, of New York, said he held that it was the duty of those who devoted themselves to special subjects to give the results of their special knowledge to their brother practitioners. He had some years ago had his attention drawn to the fact that the principle of rest in cases of inflammation applied to the throat as well as to any other part of the body. Under the influence of rest inflammatory conditions subsided, and perhaps gave way to renewed action. The larynx was moved in three functions, namely, in the production of voice, in breathing, and in swallowing. The first was a voluntary action, and it was possible therefore to secure complete rest. Breathing, though absolutely necessary for life, might be made easier, and by tracheotomy the larynx might be relieved from active participation in respiration. Was it advisable to practise tracheotomy for this purpose? He did not share in the opinion that it was a simple or harmless operation, but he considered it was valuable in appropriate cases. With regard to the third function, swallowing, tracheotomy did not afford complete rest, but other means might be taken to give partial rest.

CERVICAL RIBS.

DR. SHEPHERD, of Montreal, read a paper on three specimens of this anatomical peculiarity. Two of them were exhibited to the Section. He also demonstrated his method of strapping "caked" breast.

ECZEMA OF THE NIPPLE AND CANCER OF THE BREAST.

DR. GRANT, of Ottawa, read the notes of a case of this kind, and referred to Sir James Paget's observations, which had proved a connection between this affection and the development of breast cancer.

SECOND DAY.—SEPTEMBER 7TH.

GENERAL SESSION.—After routine business, the

REPORTS OF COMMITTEES

were proceeded with.

DR. FRANCIS J. SHEPHERD, of Montreal, presented the report on *Surgery*. He said that he merely intended to glance at a few of the more important advances made in surgery during the last twelve months in such a manner as to excite discussion. He first referred to the great advances made in the treatment of wounds, and said all surgeons aimed at antisepticism, and that Listerism was only a phase of this. Dr. Shepherd advocated the dry form of dressing wounds, and gave his own method of dressing wounds with iodoform and boracic cotton. The theories as to the cause of inflammation were then touched on, and an account given of Dr. Hamilton's experiments with sponge-grafting. He also alluded to the wonderful success of Dr. MacEwen and Mr. McNamara in osteotomy. He then remarked that no organ was considered sacred by the surgeon, and spoke of the success that has attended the operations of nephrectomy. The treatment of club-foot was alluded to, and the opinion of the members asked as to the advisability of tenotomy. The report concluded with an account of the late improvements in the treatment of the joints, and the question of excising joints for joint disease discussed.

The report elicted a full and animated discussion chiefly on the merits of the spray. Drs. Kingston, of Montreal, Canniff, of Toronto, and Brodie, of Detroit, agreeing with the reader of the report in its general inutility, while Drs. Roddick and Stewart and the President spoke strongly in favor of the full Listerian plan of treatment.

The report on *Therapeutics* was read by DR. TYE, of Chatham, Ontario. It dealt largely with the use of electricity in various affections, and the influence of different kinds of currents. In referring to the large number of new pharmaceutical preparations which had been introduced, he thought the majority of them were more beneficial to the manufacturer than to the patient.

DR. CANNIFF presented an elaborate report of the committee appointed at the Halifax meeting to seek from the government improved legislation in respect to sanitation and vital statistics. It was arranged that the committee should meet and draw up resolutions to be communicated to the Premier.

The meeting then resolved itself into Sections.

MEDICAL SECTION.

A PECULIAR FORM OF FEVER.

DR. HARRISON, of Selkirk, Ont., read a paper descriptive of four unusual cases which presented the following features: The disease came on insidiously, as a remittent fever, with slight tenderness of the bowels, hemorrhage from the nose, pain in the head and back of the neck; changed to intermittent of the quotidian or tertian type; was entirely beyond the influence of quinia, was complicated with strabismus, arching of the neck, painful contraction of the muscles in various parts so as to cause screaming or sudden piercing shrieks; ran a course of from four to fourteen weeks, two of the patients dying, one in the thirteenth the other in the tenth week. No autopsy.

In the discussion which followed, most of the speakers regarded it as a form of cerebro-spinal fever. Drs. Holmes and Tye, of Chatham, referred to similar cases.

DIPHTHERIA.

DR. MULLIN, of Hamilton, Ont., reported two cases of diphtheria—one of diphtheritic croup, in which tracheotomy was followed by a successful result; in the other the membrane appeared on the left tonsil and uvula, and the case ended fatally through septicæmia. He referred to considerations showing that it was a constitutional disease, and that local applications could not remove it.

CHOLERA INFANTUM.

DR. HOLMES, of Chatham, Ont., read a paper on cholera infantum, from which the following conclusions were deduced: 1. Secure for every child proper sanitary conditions. 2. Only resort to artificial feeding when no other course can be adopted. 3. When obliged to feed a child artificially, regulate in the strictest manner the quantity and quality of the food, and persist in none that experience shows to disagree. 4. Maintain the child's temperature at or near the normal, by means of cold sponging. 5. Avoid astringents and opiates. 6. Rely upon laxatives combined with very minute doses of hydrargyrum, frequently repeated. The importance of carrying out the fourth indication was considered very great.

NERVE-STRETCHING IN SCIATICA.

DR. STEWART, of Brucefield, Ontario, read the reports of three cases of sciatica and one of painful stump treated by stretching the sciatic nerve. One case of sciatica was cured and the remaining two greatly relieved. The result in the case of painful stump is also very satisfactory. It was shown by tracings taken during the stretchings that ether has little or no effect, while chloroform has a marked influence in reducing the blood-pressure and rate of the pulse.

TUMOR OF FRONTAL BONE COMPRESSING THE BRAIN.

DR. PREVOST, of Ottawa, reported the case of a man, aged 48, with a tumor projecting from the frontal bone on right side. It had produced exophthalmos, but very little cerebral disturbance. Coma and death ultimately supervened. The tumor had pushed back the dura mater and compressed the frontal lobe to a considerable extent.

DR. CAMERON, of Toronto, exhibited a boy with

PSEUDO-HYPERTROPHIC MUSCULAR PARALYSIS,

and commented upon the general features of the disease. He called special attention to the mode of arising from a kneeling or recumbent posture, which was very well exemplified in his patient.

DR. TEMPLE, of Toronto, mentioned a case of this disease occurring in a man aged 64.

ECHINOCOCCUS OF LIVER, BURSTING INTO LUNG.

DR. BLACK, of Uxbridge, read the notes of the case. The patient, a clergyman, had had an hepatic tumor for over four years. It had been tapped, and the diagnosis of a hydatid cyst made. Latterly septic symptoms supervened, and the spleen became greatly enlarged. Death was caused by bursting of the cyst into the lung, with the discharge of a quantity of pus. A large suppurating hydatid cyst was found in the liver; it had burst through the diaphragm. A huge single cyst existed in the spleen.

PHANTOM PREGNANCY.

DR. H. P. WRIGHT, of Ottawa, reported the case of a middle-aged woman who had borne two children; believed herself to be pregnant; thought she had quickened; and a month after the time she expected to be confined, presented an abdominal tumor and peculiar movements which simulated somewhat those of a child. It was thought at first that there might be an ovarian tumor; but on putting the patient under ether, the true nature of the case became evident.

CHEMICAL COMPOSITION OF THE MILK OF DISTILLERY-FED COWS.

DR. ELLIS, of the School of Practical Science, Toronto, together with Prof. Croft, had examined the milk of sixteen cows—eight of which were fed on distillery refuse and hay, and eight upon other kinds of food. No distinction could be made between the two classes of milk by microscopical observation, and no difference was observed as to keeping qualities. The specific gravity of the milk of the distillery-fed cows averaged 1.029, and in one case fell as low as 1.025. The specific gravity of the milk of the other cows averaged 1.032. In the milk from distillery-fed cows, the total solids averaged 14.64 per cent., and reached in one case 17.96 per cent. In the other milk the average was 12.82 per cent. The excess of solids in the distillery-fed cows is owing to an increased quantity of fat, which averaged 5.50 per cent. in the distillery-fed cows, and reached in one case 8.49 per cent. In the other cases the fat averaged 3.27 per cent.

HALIFAX AS A SUMMER RESORT.

DR. SLAYTER presented a paper showing the advantages of this city as a summer residence. The thermometer shows that in July and August, while the inland and more southern cities are liable to excessive heats, Halifax enjoys cool breezes and a very moderate temperature. The mean average temperature for July and August, during 1879–'80–'81, has been as follows: July, 61.36°, 64.83°, 61.53°; August, 61.53°, 63.03°, 64.41°.

With the exception of rheumatism, the author has observed a decided benefit in the majority of cases sent to the city during these months.

SURGICAL SECTION.

The section met at 3 P.M., DR. GRANT in the chair.

OBSTRUCTION IN THE AIR-PASSAGES.

DR. KINGSTON, of Montreal, related cases illustrating the effects of foreign bodies in the trachea and bronchi. The two most remarkable instances, viz., false tooth in the windpipe for over three months, and a pin in the trachea for eleventh months, have already been referred to in the NEWS of January 21, 1882.

POLYPOID FIBROMA OF THE BLADDER.

DR. FULLER, of Toronto, described the case, which occurred in a child one year and eight months old. Symptoms of stone were present, but nothing was discovered with the sound. Pus occurred in the urine. The child died suddenly from rupture of the bladder. The specimen was shown to the Section.

POLYPUS NASI.

DR. RYERSON, of Toronto, strongly urged the use of glacial acetic acid in these tumors, and preferred the snare to the forceps.

MODERN LITHOTRITY.

DR. WALKER, of Detroit, gave an account of several cases, with a summary of the advantages of this method of operation.

NEW OPERATION FOR HARELIP.

DR. GOODWILLIE, of New York, showed an instrument for keepting the parts together, and advised the operation immediately after birth.

AFFECTIONS OF THE ORBIT AND FRONTAL SINUS.

DR. REEVE, of Toronto, exhibited a series of photographs and specimens illustrating these affections.

EXCISION OF THE KNEE.

DR. FENWICK, of Montreal, showed a series of photographs and specimens, illustrating his last series of excision cases. Of twenty-six excisions of the knee in the Montreal General Hospital, two had died, and in two cases subsequent operation was required. One of the deaths was due directly to heart disease.

ECZEMA TREATED WITH VIOLA TRICOLOR, OR WILD PANSY.

DR. FERGUSSON reported three cases successfully treated by the internal administration of this drug.

DR. J. H. CAMERON showed three cases to the Section. A man whose thigh had been dislocated backwards, and the ilium fractured six months ago. He was still lame, and it was thought that the dislocation had never been reduced. The second case was one of ununited fracture of the femur. The third, a girl aged 20, with an enormous recurrent tumor of the upper jaw.

A paper by DR. MILLS, of Montreal, on

"MISTAKES TO BE AVOIDED IN TREATMENT OF AFFECTIONS OF THE NOSE AND THROAT,"

was taken as read.

THIRD DAY.—SEPTEMBER 8TH.

After routine business, DR. WORTHINGTON, of Clinton, Ontario, read a paper on

CLIMATOLOGY,

dealing chiefly with the subject of malaria in the Ontario peninsula. In the portion of the province bordering upon Lake Erie, the St. Clair district, and the southern end of Lake Huron, malaria still abounds, but the general opinion, obtained in answer to certain queries, is that it has lessened with the increased cultivation and better drainage. The poison seems more active after July, and a long dry period after a wet one renders it particularly prevalent.

It was suggested that, in addition to more thorough drainage and the removal of superfluous dams in the streams, the eucalyptus tree might be planted in certain districts.

In the discussion which followed, DR. MCDONALD, of Hamilton, referred to the general decrease of the disease with the better cultivation of the land. It had occurred every year in Hamilton for the past thirty years.

DR. OSLER referred to the increase of the affection in certain districts which had been hitherto almost free from it, or in which it had not been seen for some years. He believed it was spreading in the New England States and in parts of New York, about Montreal and in the city, where malaria is almost unknown, cases originating in the district had become more frequent.

THE REPORT OF THE SPECIAL COMMITTEE ON SANITATION AND VITAL STATISTICS

was then read by DR. CANNIFF.

The following resolutions were adopted:

1. That for the present the sanitary statistics shall be confined to the cities and larger towns of the Dominion, such to be published monthly, and the deductions therefrom to be circulated in the various centres specified. 2. That for future guidance in sanitary matters a commission should be appointed by the Dominion government, in order, in consultation and co-operation with the various local governments, to arrive at some common basis of action in carrying out such sanitary measures as may be necessary for the guidance of the Dominion government. 3. That such commission shall consist of at least two or more medical men with a legal adviser, whose duty it shall be to examine carefully into the various requirements of such action in sanitary matters.

The Nominating Committee reported the following

OFFICERS FOR THE ENSUING YEAR:

President, DR. MULLEN, of Hamilton.

Vice-Presidents, for Ontario, DR. TYE, of Chatham; for Quebec, DR. GIBSON, of Cowansville; for New Brunswick, DR. ATHERTON, of Frederickton; for Nova Scotia, DR. JENNINGS, of Halifax; for Manitoba, DR. KERR, of Winnipeg.

General Secretary, DR. OSLER, of Montreal.

Treasurer, DR. ROBILLARD, of Montreal.

Local Secretaries, for Ontario, DR. SAUNDERS, of Kingston; for Quebec, DR. BRUNELLE, of Montreal; for New Brunswick, DR. COLEMAN; for Nova Scotia, DR. ALMON, JR.; for Manitoba, DR. WHITEFORD.

The report was adopted and the nominees were duly elected. In the

MUSEUM

DR. SUTHERLAND exhibited a series of twelve specimens illustrating some of the *Modes of Termination of Aneurism.*

DR. OSLER exhibited slides of the *Bacillus of Anthrax*, and the *Bacillus of Tuberculosis.*

DR. GRAHAM exhibited slides of *Koch's Tubercle Bacillus and Ponfick's Actinomycosis.*

After the usual vote of thanks, etc., the meeting adjourned at 12.30.

The members of the Association were entertained by the Toronto profession at a conversazione on Thursday, and on Friday afternoon Dr. Clark gave a luncheon at the Asylum for the Insane.

The next place of meeting is fixed for Kingston, Ontario, on the first Wednesday of September, 1883.

MEDICAL SOCIETY OF VIRGINIA.

Thirteenth Annual Session, held at Fauquier White Sulphur Springs, September 13, 14, and 15, 1882.

(Specially reported for THE MEDICAL NEWS.)

FIRST DAY. AFTERNOON, SEPT. 13.—The Thirteenth Annual Session of the Medical Society of Virginia convened at 3.45 P.M., Wednesday, September 13, 1882, at Fauquier White Sulphur Springs, Va. Because of the illness of the *President*, DR. G. WM. SEMPLE, of Hampton, Va., the *First Vice-President*, DR. W. L. ROBINSON, of Danville, Va., assumed the chair. The *Recording Secretary*, DR. LANDON B. EDWARDS, of Richmond, was in place.

ADDRESS OF WELCOME.

DR. JOHN MCILHANEY, of Warrenton, President of the Fauquier County Medical Society, introduced HON. J. G. BROOKS, of Warrenton, who, on the part of the medical profession and citizens of that section of the State delivered an address, in which a cordial welcome was extended.

A LETTER FROM THE PRESIDENT

(Dr. Semple) was then read, in which he expressed his great disappointment and regret in that he was unable to attend, etc. This letter, on motion, was ordered to be published in the annual volume of *Transactions*, and a vote of sympathy was given by the Society.

Dr. John N. Mackenzie, of Baltimore, Md., was then introduced as a

FRATERNAL DELEGATE

from the Medical and Chirurgical Faculty of Maryland. He was invited to a seat in the body and to participate in the discussions that might come up during the session.

In the absence of all the members of the standing

COMMITTEE ON NOMINATIONS OF APPLICANTS FOR FELLOWSHIP

in the Society, the Chair appointed a committee of five to act in their stead. The committee *pro tem.* was composed of Drs. J. E. Chancellor, of Charlottesville; C. C. Conway, of Rapidan; John R. Wheat, of Richmond; G. Wm. Pollard, of Ayletts, and Bedford Brown, of Alexandria. In a short while this committee reported favorably upon all the applications presented. [During the session forty or more new members were added—one of the largest additions to the membership of the Society during any one year for ten years.]

THE REPORT OF THE RECORDING SECRETARY

showed the receipt of the usual number of exchanges; the issue of two "certificates of fellowship;" the disclaiming of membership of another member; the dropping of two other members from the Register; the registration of two members who report themselves as over 70 years of age, and consequently no longer responsible for dues or assignments; the resignation of five members—three because they had removed from the State, and one who had retired from practice; one doctor should have been reported last year as having resigned; information of the deaths of only two Fellows during the year has been received. Present membership of the Society, including those who joined during this session, about 460.

On motion of Dr. S. K. JACKSON, of Norfolk, a committee of five was ordered to be appointed to express the sense of this Society in regard to the action of the New York Medical Society during its last session which relates to the change of the

CODE OF ETHICS

of the American Medical Association, and which proposed change admits of consultation on the part of regular practitioners with irregulars. The acting President appointed Drs. S. K. Jackson, M. L. James, of Richmond; O. H. Baird, of Waverly; Wm. D. Cooper, of Morrisville; and M. A. Ish, of Neabsco Mills; with instructions to report to-morrow morning. The

REPORT OF THE NECROLOGICAL COMMITTEE

was then presented by letter from the Chairman of the Committee, Dr. John S. Apperson, of Town House. The report was referred, without reading, to the Committee on Publications.

MISCELLANEOUS BUSINESS.

DR. JOSEPH A. WHITE, of Richmond, offered a resolution requiring the attendance of every member at the session at which he may be elected to any office in the gift of the Society. This suggestion awakened a lively discussion, and, after a lengthy debate, it was agreed that a vote should be taken on the subject to-morrow morning, without further remarks.

On motion, a committee of thirteen Fellows was ordered to be appointed at once to nominate officers—other than the President and Assistant Recording Secretary—for the ensuing year.

The Society then adjourned until 8 P.M.

EVENING SESSION.—SEPTEMBER 13TH.

As soon as the meeting was called to order, the acting *President* (DR. ROBINSON) made a few remarks as a substitute for the

PRESIDENT'S ADDRESS.

He greeted the members with a joy born of twelve months' pleasurable anticipation. To those either too careless to investigate, or too ignorant to appreciate, the advantages of sustaining a State Medical Society, he proffered his profound pity. The life of this Society meant sustenance of medical ethics, brotherly love, advancement by study and principle to the standard to which each one is eligible. In regard to other matters, he thought that Richmond was the best place for annual meetings, especially during the week of the usual annual agricultural fair, which occasion always attracts a large number of practitioners to that city, in company with the crowds of other citizens from all sections of this and adjoining States. Forbid banquets by the local societies. He favored the election of a President at the beginning of a session. He urged that papers read before a meeting should be discussed before reference to the Committee on Publication. The "Ex-President's Prize," as offered this year, is undoubtedly a step in the right direction. After a complimentary allusion to the worth of the President of this Society, and an expression of sympathy because of his present ill-health, which alone prevents his attendance, he closed by congratulating the doctors of this section because of the large additions made by them to the membership of this Society.

The reports of the Standing Committees on Progress in the various departments of medical science—the first presented (by the author) was the

REPORT OF THE COMMITTEE ON SURGERY,

of which the following is an abstract:

DRAINAGE IN GUNSHOT WOUNDS.

DR. HUGH M. TAYLOR, of Richmond, Va., limited his report to a consideration of the value of drainage in gunshot wounds. He showed the important part which drainage plays in the treatment of all classes of wounds, by referring to the "open method," to Callen-

der's and Lister's methods; to the cotton-wool dressing of Guerin; to the dry-dressing of Gamgee, and to the sponge dressing, recently made prominent in this country by McClellan. In all of these most prominent methods of treating wounds, now in vogue, drainage is secured and forms the most important adjuvant. In a class of wounds, defined as contused and lacerated, in which sloughing, granulation, and cicatrization invariably occur, and in which there are many conditions to prevent free escape of inflammatory products, we must find free drainage of the greatest importance. The means of securing drainage, which he mentioned are position, incision, dilatation, rubber tubes, glass tubes, decalcified bone, strands of horsehair and silk tents, canula, and such other agents as sponge, absorbent cotton, cotton-wool, etc., which exert capillary attraction.

After dwelling upon the local and constitutional good secured by drainage, the importance of drainage in gunshot wounds of special parts was considered. Few surgeons now question the advantage of treating suppuration in joints by free incision, drainage, and antiseptic washes. Penetrating gunshot wounds of the joints are invariably attended with suppuration, which should also be treated by free incisions, drainage, and antiseptic washes. In gunshot wounds of the extremities, we are taught the value of drainage by the good it effects in compound fractures of the extremities. In pyonephrosis and rupture of the kidney, the indications are clearly in favor of free incision, and the use of drainage-tubes, to evacuate collections of pus or urine; and the success which attends this treatment points clearly to the course to be pursued in gunshot wounds of the kidney. The early removal of blood, serum, pus, and urine is the keynote to the successful treatment of such wounds. In abscesses and cystic disease of the liver, more reliance is placed in aspiration, free incision, and drainage, and in gunshot wounds more reliance should be placed in free incision, drainage, and antiseptic washes. The mortality which follows gunshot wounds of the liver, treated upon the expectant or do-nothing plan, warrants a resort to active operative interference. The indications in favor of drainage in gunshot wounds of the bladder are too plain to admit of discussion. To prevent its consequences, such as pelvic cellulitis and peritonitis, nothing can take the place of drainage. In no gunshot wounds is drainage more important than in those of the head. To prevent compression by the retention of inflammatory products, to avoid blood-poisoning, and to encourage repair of the local injury, drainage is absolutely needed. No sutures and no plaster after penetrating gunshot wounds and after trephining should be used—only some light absorbent dressing.

The cases of penetrating gunshot wounds of the chest which recover, are the cases in which thorough drainage has been practised. No surgeon now thinks of hermetically closing a penetrating wound of the chest. On the contrary, we are instructed to keep the wound open—of course the most dependent, if there are two wounds; and even, if necessary, to make a free counter-dependent opening and introduce a drainage-tube. In empyema, great good is accomplished by aspiration, paracentesis, incisions, drainage-tubes, and flushing out the cavity; and the analogy between the consequences of gunshot wounds and empyema is too striking to be overlooked. In the loose cellular tissue of the mediastinum, suppuration is active and large collections of matter resulting in pyæmia and death is a frequent sequence of gunshot wounds of this region. If nature's efforts are found to be inadequate to the task of securing perfect drainage, they should be aided by incisions; and, if necessary, by the introduction of a drainage-tube. Rosenstein, of Leyden, has recently drained a suppurating pericardium by means of a draining-tube. His case is unique, in that it is the first in which the pericardium has been opened and a drainage-tube introduced with the specific object of removing purulent fluids. The success of this case points clearly to the best treatment for penetrating gunshot wounds of the pericardium which are not immediately fatal. The value of drainage, in penetrating gunshot wounds of the belly, is attracting more attention than any subject connected with the treatment of gunshot wounds. Attention was first called to this subject by Dr. Hunter McGuire, of Richmond, Va., in 1873. Afterwards by Dr. Marion Sims, of New York, and again by Dr. McGuire in 1881, during the session of the American Medical Association. Over 92 per cent. of the patients operated upon for ovariotomy recover. Over 90 per cent. of gunshot wounds of the peritoneum die. In the former, and not in the latter, the importance of thorough drainage has been appreciated. Operative interference to repair the injury done and to secure perfect drainage is of the last importance in penetrating gunshot wounds of the belly.

The conclusions arrived at by the writer, are:

1. That union by primary adhesion is exceedingly exceptional in gunshot wounds.
2. That suppuration, granulation, and cicatrization, are invariably combined in the process of repair.
3. That extensive accumulations and burrowing of pus in a deep, narrow bullet track, are to be expected and feared.
4. That the deep, narrow, angular, and frequently-obliterated track does not afford perfect drainage.
5. That in such cases the principles of surgery applicable to other deep-seated suppurations must be applied.
6. That position, incision, dilatation, drainage-tubes, and the other means mentioned, are of great importance in treating the consequences of gunshot wounds.
7. That, by nature's efforts, analogy, and reason, we are taught to think that their more frequent use will lead to better results in this class of injuries.
8. That the danger incident to their use is far outweighed by the benefit which accrues.

On motion, this paper was referred to the Committee on Publications, with authority to publish.

DISCUSSION.

DR. R. I. HICK'S, of Casanova, remarked, in regard to gunshot wounds of the chest, that if Dr. Taylor meant that drainage-tubes should be introduced to anticipate any collections of noxious matters, he could not endorse the suggestion, because he had seen too many cases of gunshot wounds of the chest recover without any bad symptoms, upon the expectant plan. But he supposed that all surgeons of the present day agree that collections of pus or other offending matters should be evacuated, if practicable, wherever found. This principle is as old as the fathers of medicine.

He had also seen several wounds of the abdomen recover in like manner; and, even in these cases, interference should be withheld until it was ascertained that offending matters were either retained, or were in the act of formation. If formed, he entirely agreed as to the importance of early removal or evacuation—because under the non-interference plan in such cases, death almost inevitably results.

DR. J. E. CHANCELLOR, of Charlottesville, spoke of two cases met with in his practice bearing upon the point at issue. The first case he alluded to was that of a Confederate soldier, of high position, who, during one of the battles of the Confederate War, was wounded between the sixth and seventh ribs of the right side. The Minie-ball came out under the lower angle of the scapula of the same side of the body. There were ex-

pectoration of blood and the other usual signs of complete perforation of the lungs, the pleura and the chest walls. In a few days, pus formed; some was expectorated and some passed out through the wounds of entrance and exit; there was also some pleuritic effusion. This condition, of course, was attended by cough and dyspnœa. The soldier was brought to the hospital at the University of Virginia, of which Dr. James L. Cabell, Professor of Surgery in that institution, had charge. An opening was made with the knife along the lower border of the sixth rib, and eight or ten fluid ounces of pus were drawn off. After this operation, the patient fell into the hands of the reporter [Dr. Chancellor]. Carbolic washes of the wound—externally and by injections—were resorted to, and drainage by means of a gum catheter was adopted as the general line of treatment, with such supporting regimen as seemed required from time to time. In addition, treatment by position was followed out, so as to let either one or the other of the external wounds be dependent, so as to facilitate drainage. This plan of treatment was kept up for some weeks or two months, by which time restoration to health was rapidly advancing. The body was then noticed to be much "drawn" to the right side. Within a few months, however, the lungs were invaded by deposits, which appeared to be tuberculous, and the patient died. Still, the lesson learned from this case was "the value of drainage of gunshot wounds;" for the patient, after recovery from the wounds themselves, was able to ride about or go where he pleased; and while he did complain occasionally of "stitching pains" at the points of both wounds for some time afterwards, as well as "heavy pains" along the track of the wound through the lung, it was several months later that the tubercular trouble began. The doctor *knew* nothing about the history of consumption in the family of the patient.

The other case bearing on this subject, was that of a married lady, of some thirty years of age from Texas, who, ten years ago, while dancing one of the round dances, as she professed, had her right side too much compressed. She was not "well" at the time of her dancing; but being fond of the amusement, she danced immoderately, whenever opportunity offered. But soon after the special dance referred to, she had hepatitis, followed by an abscess of the liver, which "pointed" on the right side between the ninth and tenth ribs. An incision was made in the most dependent part, so as to evacuate the pus. After this, "a drainage position" was directed. Then a drainage-tube was inserted, but it did not act well; it became clogged too frequently to accomplish the ends in view. In studying how to promote the discharge of purulent matter from the cavity of the abscess, he determined to resort to properly applied compression. He adopted a specially prepared spring truss—the drainage-tube being frequently taken out for cleansing purposes, and re-inserted. This treatment was kept up for a month or more, under Dr. Chancellor's care, when she was sent to the Rockbridge Alum Springs, Va., where the resident physician, Dr. Saml. B. Morrison, followed out the same general line of treatment as had been pursued, chiefly, draining locally, and tonics internally. She recovered her health perfectly, so far as known, to this day.

Dr. Samuel C. Gleaves, of Wytheville, addressing Dr. Chancellor in regard to the last mentioned case.—"Was the drainage-plan of treatment the cause of the cure?"

Dr. Chancellor.—"Yes, I believe it was."

Dr. Gleaves.—"If the pointing abscess had simply been lanced sufficiently at the most dependent point, and the proper position of the patient been ordered and followed out by the nurse, would not sufficient drainage have been kept up?"

Dr. Chancellor.—"Yes; but with the carelessness of nurse, or disobedience of patient, it is impracticable to depend upon the exact following out of such instructions. Of course, you must be careful, under such circumstances, to keep the incision wound open."

Dr. Gleaves.—"What, then, is the use of the additional irritation caused by the insertion of a drainage-tube?"

Dr. Chancellor.—"I do not admit that the proper introduction of a properly devised drainage-tube causes improper irritation. It frequently happens that the very irritation caused by the gentle introduction of a draining-tube into a deep abscess of any part of the body creates exactly that kind of 'irritation' which is most desirable for repair of an indolent ulcer or abscess." In furtherance of these views, he mentioned the case of a man who was shot laterally in his knee-joint—the ball going through and through. Such cases generally end fatally, unless amputation of the thigh is undertaken; and even then many failures of success occur. In the case briefly reported by him, the drainage-tube plan of treatment was adopted, and the patient thoroughly recovered, with the exception that he left with an anchylosed knee. "Was that not better than having either an artificial limb, or an amputated thigh?"

Dr. Gleaves then referred to a case, some time ago under his charge, of abscess of the liver. After opening it, he could not get it to heal while pus was flowing from it, or while it was secreting.

A Member.—"Of course not. Ought to have inserted drainage-tube, and thus have caused sufficient inflammatory irritation. Dr. Gleaves himself said, '*ubi fluxus, ibi irritatio.*' The flow ought to continue when there is no irritation, and for a stronger reason ought to continue while there is irritation of the abscess."

Dr. Taylor, the author of the paper under discussion, referred to the autopsy of a case which had induced him to believe in drainage wherever there was deep-seated abscess, or even wherever a superficial one, of large size, with its external opening was constantly clogged up. He believed in drainage, especially in all major operations. If position or the patency of the opening would not permit proper drainage of the foul matter—whatever that matter might be—then establish a means artificially for free drainage. If the chimneys of a closed house do not carry off the poisonous effluvia of a house, then let the doors and windows be opened. So in regard to abscesses or poisonous effusions in the abdominal cavity. If the opening by the wound of entrance or exit is not sufficient to admit of drainage—the escape, indeed, of the poisonous secretion, whatever may be its character—then make an artificial opening intelligently, and keep in this wound a perfectly secure drainage-tube—whatever may be the kind or shape of the drainage-tube required for the special case under charge.

Under call for volunteer papers or reports, Dr. Hugh T. Nelson, of Charlottesville, reported the following case of

URETHRAL STRICTURE OF TWENTY YEAR'S STANDING, IN WHICH PERFECT CURE OF THE LESION WAS AFFORDED BY THE VIS MEDICATRIX NATURÆ ALONE.

The case was one of unusual interest.

Mr. B., a country farmer, aged 63. He has had attacks of gonorrhœa in his younger days, and hence became the subject of retention of urine. He applied for treatment on May 4, 1882. He had had stricture of the urethra for twenty years, and had been under physicians of prominence previously, but no operation had ever been performed. On the day named, however, after continued and violent efforts at micturition, the

bladder had been emptied before the doctor saw him; he had suffered great pain for several hours, and had evidently only been relieved by the relaxation following upon intense vesical distention. A No. 5 bougie was introduced, passing, on its way to the bladder, through the cartilaginous strictures, one embracing nearly an inch of the urethral extent, the penis being very large, and seemingly œdematous. Mr. B., with considerable difficulty, managed to keep the bladder comfortably empty until the 9th, when complete occlusion of the urethera forced him to seek professional assistance. The No. 5 bougie was passed, but with great difficulty, from the contracted state of the stricture; and after the beak of the instrument had entered the bladder, the grasp of the stricture was so great as to prevent further introduction. The bougie was withdrawn with great difficuity, and a smaller catheter passed, which cut the urethra a little, but emptied the bladder perfectly and with great relief.

The patient now called attention to an enlargement in the corpus spongiosum; an examination of this showed at about the middle of this portion of the urethra, and consequently covered by the scrotal folds, something that appeared to be a fibrid growth, about the size of a pigeon-egg, and corresponding to the most undilatable of the strictures. He was seen daily for several days, and the bougie was used regularly with apparent improvement in the condition of the stricture. On the 13th he was so much relieved that he declined further treatment, and determined to return home on the 15th. About noon on the 14th, however, the doctor was summoned in haste, and found the old man suffering great pain, and straining violently in ineffectual efforts to empty the bladder. The scrotum was found enormously distended; its more superficial tissues were very much thickened and hardened. No fluctuation was detected, the absence of which, together with an entirely normal state of the *perineum*, made it highly probable that the condition was due to erysipelas of the superficial and deep tissues, though the possibility of urinary infiltration was not lost sight of. The bougie was passed with relief, and the ordinary treatment appropriate to an erysipelatous condition of the parts was instituted. On the morning of the 15th a large patch of gangrene occupied about three-fourths of the now enormously distended scrotum, from which the cuticle was entirely gone, and a fetid, sanious ooze escaped. Early on the 16th, there was no further extension of the gangrene, and a line of demarcation was visible; but the œdema was extending upon the pubis, the perineum still retaining its natural condition. On the evening of this day, Prof. J. S. Davis, of the University of Virginia, saw the patient in consultation, and gave, as his opinion, that the case was one of urinary infiltration, consequent upon rupture of the spongy urethra, and the diagnosis was immediately verified by the modified operation for *anterior perineal section*, which was performed by Dr. R. W. Nelson, of Charlottesville, Va. Over one pint of urine, and several ounces of pus escaped from the incision, and for several days urine dribbled from the wound, small quantities being also discharged from the meatus several times each day. Except on the two occasions mentioned there had never been perfect retention, and the urine, though passed in small quantities, had always seemed to reach a fair twenty-four hour average. A stimulant and tonic treatment was kept up; the large gangrenous mass sloughed away, exposing both testicles, which were covered by the tunica vaginalis alone; the amount of urine passed through the meatus continued to increase, accompanied by a corresponding diminution in the quantity which passed from the large wound. The granulations were most satisfactory, and by the first of July both testicles were completely enveloped by a good healthy scrotum, accompanied, it is true, by retraction of the penile integument, which renders perfect erection impossible. The strictures are entirely relieved, and the urine is passed in a fuller stream than ever before, and this, although neither catheter or bougie was ever introduced into the urethra after the operation.

DR. NELSON, in connection with this subject, exhibited a

CATHETER BOUGIE,

as made and used by Dr. R. W. Nelson, of Charlottesville, Va., in cases of urethral relaxation and prostatic trouble, in which even the eye of a soft rubber catheter occasioned sometimes troublesome hemorrhage. The instrument is always introduced in its bougie form, then opened to empty the bladder, and *never* to be closed until *after* withdrawal.

After the reading of Dr. Nelson's paper, DR. GEO. B. JENNINGS, of Ruckersville, was requested to report, in full,

AN UNUSUAL CASE OF SLOUGHING OF THE PENIS AND SCROTUM,

and promised, by request of several members, to report in full, in writing to the *Transactions* of the Society for this session. The chief point of interest in the case was that of ulceration of the under portion of the penis and the major part or the scrotum, including the testicles, leaving several urethral sinuses or openings between the bladder and the mouth of the urethra.

After this report the meeting adjourned until 10 A.M., Thursday.

(*To be continued.*)

CORRESPONDENCE.

HYPODERMIC INJECTION OF WATER FOR THE RELIEF OF PAIN.

To the Editor of THE MEDICAL NEWS.

SIR: The case reported by Dr. S. J. Radcliffe in THE MEDICAL NEWS of September 2d, reminds one of a somewhat similar experience. In the year 1873 there came under my care, sent to me by a neighboring physician, a woman, between 45 and 50 years of age, widow, with sciatica. She said that she had been afflicted a long time, and had been treated by a number of physicians, all of whom had administered either opium or morphia, and that the one who had sent her to me, Dr. W., was the first one to use the hypodermic syringe. The woman seemed to suffer, and although she was a "spotted specimen" from previous punctures, I followed the same treatment, and "smote" her hip and thigh with the hypodermic, injecting the morphia solution daily, sometimes twice. For many days I continued this treatment, always with relief temporarily. Finally, it ocurred to me to try a little deception, and give a hypodermic injection of water. I expected my patient would return that day for another dose, but she did not. The next morning I again used the distilled water, as it gave the desired relief, and continued these injections for about two weeks. Then I told "me leddy" that she was cured; that she did not need any more morphia; that I had been injecting water. Well, she just swore and tore around, and let fly at me from her sainted lips some choice appellations, which would show up too handsomely on paper, so I forbear. To persuade her to leave the office, I informed her that I would be under the necessity of calling in an officer. This had the desired effect. She went muttering something that sounded like "report you to the health officer" (I was district physician to

the Ninth Ward of this city then); "put you in the papers," etc. It was not long until I happened to see her in another physician's office; I told the gentleman, Dr. W. J., what I had done, and after that he tried the hypodermic water treatment for a few days until he was satisfied that the woman did not need the morphia, and discharged her, and, I believe, informing her, as I had done, of the watering process.

Respectfully,
R. D. MUSSEY.

N. W. CORNER FOURTH AND ELM STS., CINCINNATI,
September 14. 1882.

A SPLINT TO REPLACE THE STROMEYER.

To the Editor of THE MEDICAL NEWS.

SIR: The splint which I described in your issue of August 26 was made for me by Mr. Gemrig, in September, 1881, and, therefore, really ante-dates Dr. DeYoung's (described in the NEWS of September 16) by six months. At the same time, I have little doubt that others have had virtually the same splint made long before either of us. So far as I am aware, however, no such splint has been described before, and certainly none is in common use. The chief defect of the Stromeyer splint—its limited flexion—and also the ill-effects of the pressure at the joint, are both remedied by either form of splint.

Very truly yours,
W. W. KEEN, M.D.

PHILADELPHIA, September 18, 1882.

NEWS ITEMS.

TREATMENT OF YELLOW FEVER.—From the Secretary of the National Board of Health, we have received the following for publication: The United States Consul at Maricaibo (Mr. Plumacher), in a recent communication to the State Department, enclosed the translation of an extract from a Venezuelan journal, *The Opinion Nacional*, of July 31, 1882, concerning the treatment of yellow fever, by Dr. Serafia Sabucedo Varela, of Havana, Cuba. The extract was referred by Mr. Hunter, Second Assistant Secretary of State, to the National Board of Health, and was by it directed to be published. The translation is as follows:

"REMEDY FOR YELLOW FEVER.—The Havana newspapers which we have received to-day contain the following remarks, accompanied with high recommendations. Yellow Fever. The writer of these lines, doctor of medicine, certifies that since the 24th of June, of the present year, he has used as a remedy against yellow fever, doses of salicylate of sodium and carbolate of sodium, administered in spoonfuls, which remedies have been attended with the happiest results in 15 cases of this deadly disease.

"Dr. Sabucedo does not warrant in any way that these remedies will be always successful, since a number of observations are necessary to determine the truth of such a transcendental fact for afflicted humanity, and he also rejects energetically every idea of charlatanism or speculation, desiring only to call the attention of his worthy and instructed colleagues, in order that the field of observation may be extended as much as possible, for the purpose of demonstrating by facts, whether or not these remedies offer a veritable specific against such a formidable enemy. The curative system is as follows:

"Before the lapse of 48 hours from the first symptoms, administer rapidly an emetic and whatever purgative.

"After these have operated, give, without loss of time, the following formulas:

"No. 1.—Salicylate of sodium, . 4 grammes.
Water, ... 100 "
"No. 2.—Carbolate of sodium, . 1 gramme.
Water, ... 11 grammes.

"Commence to use these formulas as soon as the purge operates, beginning with a spoonful of No. 1, then wrap the patient, and in one hour administer a spoonful of No. 2, thus administering every hour until both formulas are exhausted.

"The alarming phase will then have disappeared; the patient perspires and on the second day the fever descends to a less grade, and there is no longer danger, the patient having the assurance that he is saved.

"With this treatment it is very rare to meet with vomit, with albuminuria, or retention of urine, the symptoms limiting themselves to bleeding at the gums and nose, the blood being bright and healthy. The urine is clear and slightly yellow, and occasionally green, without precipitating, after the fourth day.

"It can be said that serious yellow fever transforms itself, by this simple treatment, into a mild or abortive yellow fever, and no patient has as yet died among those treated on this plan.

"(Signed) DR. SERAFIA SABUCEDO VARELA."

"HAVANA, July 18, 1882."

YELLOW FEVER.—The yellow fever at Pensacola has spread rapidly during the past week, the total number of cases since the presence of the disease was acknowledged amounting to 217 on the 18th inst.—29 deaths having occurred in the same time. Up to September 12th, there were 114 cases and 19 deaths.

Not long since, the reports from the city indicated that the shipping was free from the disease, but on the 17th an Italian bark, the "Galileo," from Pensacola, was telegraphed as passing between the capes bound for Hampton Roads, with four persons on board dead from yellow fever. The vessel was taken to the quarantine barge, near Craney's Point, at the mouth of the Elizabeth River.

The estimates of the City Board of Health, forwarded for the approval of the National Board, called for an expenditure of two hundred dollars a day, of which fifty dollars daily were required for disinfectants. The National Board of Health allowed one hundred and fifty dollars daily for nurses and inspectors, and ordered disinfectants remaining on hand from the epidemic of 1879 to be forwarded from Memphis. There is great difficulty experienced in obtaining nurses for the sick. The disease has occurred mostly among those who are unable to pay the charge of five dollars a day for nursing, and this item constitutes a heavy draft on the funds of the health authorities. No effort has been made by the local board to establish hospitals, although the bills for nursing would thereby be considerably reduced. It is certain now that Pensacola will have to suffer until the thermometer falls, or until, as in Brownsville, all the susceptible persons have suffered.

The Spanish bark "Saleta," in which the Pensacola fever is said by some to have originated, and which was towed to sea on August 10th, has been heard from at Havana. Dr. D. M. Burgess visited her there and found that the two men who were sick at the time the vessel was sent from Pensacola, died on the voyage,

and that none of the other persons on board sickened with the disease; but inasmuch as some of them had certainly suffered from fever in former years, while the history of the others rendered their susceptibility doubtful, their escape cannot be used as an argument that the disease on board was not yellow fever.

In Texas the disease has not spread beyond the line guarded by the Marine-Hospital Service, but it has extended up the river from Matamoras, on the Mexican side, to several towns, as Reynose and Mier. Guards have been placed opposite these points to prevent its introduction into the Texan settlements.

On September 5th, a case of fever occurred in New Orleans which gave rise to some anxiety, as it appeared in the locality which is acknowledged as having been recently infected. It was ultimately pronounced by the State Board as one of bilious remittent.

While Louisiana is quarantining against Pensacola and Brownsville, her neighbors manifest their fear of infection from New Orleans by demanding the inspection certificate of the National Board of Health on all freights coming from that city by river or rail. On September 11, Governor Roberts, of Texas, approved "regulations" drawn up by Dr. Swearingen, Health Officer of the State, for the transfer and disinfection of freight passing through the disinfecting warehouse near the Sabine River, during the existence of quarantine against New Orleans. On the 6th instant the State Board of Mississippi required the extension of the inspection service to passengers as well as freight.

As there was no yellow fever in the city at the time, the Louisiana Board and New Orleans papers charged the National and Mississippi Boards with conspiring to cast odium on the city, injure its trade, and annoy the travelling public. This drew from the latter Board at its meeting, on the 12th inst., a resolution, in which it declared and proclaimed its full and entire responsibility for any and all steps taken heretofore in establishing the system of inspection now in force against New Orleans. It is to be hoped that the season will pass without giving the Mississippi Board occasion to congratulate itself on the wisdom of a precaution which places the guards in position to be ready for an emergency which may occur at any moment.

The following summary of the progress of the yellow fever is reported by the Surgeon-General of the Marine-Hospital Service, for the week ending September 16, 1882, at

BROWNSVILLE, TEXAS.

CHOLERA IN JAPAN.—Recent advices from Japan give the number of cases of cholera in Yokohama, from August 10th to 21st, as 608, with 357 deaths. The total figures from the beginning of the epidemic amount to 2,801 cases and 1,719 deaths, a mortality of over 61 per cent. The foreign residents continue free from the disease. Other parts of the Empire are becoming infected. Osaka, one of the largest cities, has been declared an infected port.

CHOLERA IN THE PHILIPPINES.—Official dispatches have been received at Madrid from the Philippine Islands, confirming the increase of cholera, and causing great alarm. Hitherto only natives had been attacked, but the deaths of several Europeans are now reported. Four thousand natives have died from cholera in a single province. The epidemic is, however, believed to be now decreasing. The government has adopted most stringent measures regarding vessels arriving at Spanish ports from the East.—*British Med. Journal*, September 2, 1882.

TUBERCLES AS MANIFESTED IN THE LARYNX.—At the conversational meeting of the Pathological Society of Philadelphia, to be held in the Hall of the College of Physicians, on Thursday evening next, DR. J. SOLIS COHEN will read a paper entitled "Tubercles as Manifested in the Larynx." Dr. Morell Mackenzie, of London, we understand, is expected to take part in the discussion. The profession is invited to be present.

RESIGNATION OF PROF. PIRRIE, OF THE UNIVERSITY OF ABERDEEN.—Dr. Pirrie, the venerable Professor of Surgery at Aberdeen, has resigned his chair on the ground of advanced years and declining health. At the meeting of the University Court held last week permission was given, and, after the members had individually expressed their high sense of the distinguished services of Dr. Pirrie, it was agreed to recommend that an increase of the usual retiring allowance should be granted. Dr. Pirrie has served the University in the capacity of Professor for the long period of fifty-two years; for nine years as Lecturer on Anatomy and Physiology, and since then in the now vacated chair.—*Lancet*, September 2, 1882.

THE DUKE OF ALBANY.—According to the *Lancet*, his Royal Highness suffers from constitutional weakness, with liability to hemorrhage—hæmatophilia.

DARWIN'S STATUE.—Twelve thousand five hundred dollars have been already collected for the marble statue of Darwin, to be erected in the British Museum.

PERSONAL.—The American Rifle Team, which participated in the late international match at Creedmoor, had for one of its members the well-known pathologist, Dr. E. O. Shakespeare, of Philadelphia.

DR. GEORGE CAPRON, eighty years old, and the oldest practising physician in Providence, received a shock of apoplexy Sunday, and is reported to be dying.

TO DISGUISE THE TASTE OF QUINIA.—MR. J. K. LILLY proposes the syrup of yerba santa for the above purpose. Very little seems to be known about this substance. The purest state in which the writer has as yet been able to obtain it is in the form of an amber, mucilaginous mass, soluble in water and alcohol, insoluble in ether, benzine, and chloroform, precipitated by strong acids, and re-dissolved by alkalies. It may be prepared by mixing a fluid extract, made with a menstruum of not less than 75.9° alcohol, with an excess of water, boiling to drive off alcohol, shaking with finely powdered pumice, allowed to stand, then filtering and the filtrate evaporated to the consistency of an extract. The following formula is proposed for the preparation of a syrup, which has proved to be very satisfactory:

Fluid Extract Yerba Santa, . .	4 parts.
Water, ...	8 "
Powdered Pumice, ...	1 "
Granulated Sugar, ...	14 "

Mix the fluid extract with the water, evaporate to seven parts, shake with pumice, allow to stand, decant, add sufficient water to preserve measure, then with heat dissolve the sugar. The addition of fluid extract of licorice in the proportion of half a drachm to the ounce of syrup, or of aromatics, adds somewhat to the elegance of the preparation. When quinia or other bitter substances are suspended in this syrup their taste is completely masked. It is far superior to the licorice preparations used for the same purpose, is pleasant and agreeable, and is easily prepared.—*Chicago Med. Rev.*, August 15, 1882.

BELL-RINGING A NUISANCE.—The Supreme Judicial Court for Plymouth County, Massachusetts, has just enjoined Francis A. Sawyer and others, from ringing a bell upon their woollen mill in Plymouth. The case came to the full court on appeal by the defendants from a decree entered by a single justice, enjoining them from ringing the bell earlier than half-past six o'clock in the morning. The plaintiffs for many years have owned and occupied dwelling-houses situated, one about 1000 feet and the other about 300 feet from the defendant's woollen mill. The defendants commenced to run their mill, which had been previously occupied by other parties, in December, 1879, and about January 1, 1880, placed the bell upon the mill and caused it to be rung every working day at five and twice between six and a half o'clock in the morning and at other times during the day, except that the five o'clock bell was discontinued during the summer. The plaintiffs alleged that the bell as rung was a private nuisance to them and injured their property and disturbed the quiet and comfort of their homes; that it was not necessary for any purpose of trade or manufacture; that it was unnecessarily large and rung at unreasonable hours and unreasonably long. The defendants in their answer denied that the bell was a nuisance to the plaintiffs, and alleged that it was used by the defendants to summon the operatives in their mill to work; that it was necessary and customary to adopt some method to summon operatives in such a manufactory to their work; that the bell was of suitable size, rung at suitable hours, and in a proper manner for that purpose. Two questions were presented for the consideration of the court: First, whether the plaintiffs proved that the ringing of the bell was a nuisance to them; and second, whether it was such a nuisance that the court would interfere to restrain it by injunction. The court has now decided that the evidence seemed fully to sustain the finding of the judge who heard the case—that the ringing of the bell was a nuisance to the plaintiffs, and further, that the plaintiffs were entitled to an injunction. The decree of the single justice was accordingly affirmed.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending September 9, 1882, indicate that dysentery and typho-malarial fever have considerably increased, that erysipelas and influenza have increased, and that diarrhœa and tonsillitis have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending September 9, and since, at 17 places, scarlet fever at 11 places, measles at 4 places, and smallpox at 3 places, as follows: in Berlin Township, Ionia Co., September 8; at Grand Rapids (last case discharged September 12); at Ionia, September 18.

For the week ending September 9, the sanitary inspector reports 3 cases of whooping-cough among immigrants arriving at Detroit.

OBITUARY.—A cable dispatch from London announces the death, on September 15th, of SIR JAMES ALDERSON, the eminent physician. He was the son of Dr. John Alderson, of Hull, and was born there in 1800. He graduated at Cambridge as sixth wrangler in 1822, and became a fellow of Pembroke College. After a course of studies in Oxford he took his degree in 1829 and achieved success as a practitioner in London. He published a treatise on *Diseases of the Stomach* in 1847, and delivered the Lumleian course of medical lectures in 1853-4. Soon after he was made fellow of the Royal Society, and was president of the Royal College of Physicians four successive years, from 1867 to 1870. He was appointed physician extraordinary to the royal household, and was knighted in 1869. The degree of doctor of civil law was conferred on him by the University of Oxford in 1870.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 11 TO SEPTEMBER 18, 1882.

BACHE, DALLAS, *Surgeon.*—Informed by Adjutant-General of acceptance of his certificate of disability of August 31, 1882, on sick leave, from September 1 to 30, 1882.

MADDOX, T. J. C., *Assistant Surgeon.*—To proceed from Fort Clark, Texas, *via* San Antonio and Laredo, to Fort Brown, Texas, for duty.—*S. O. 96, Department of Texas, September 8, 1882.*

WRIGHT, J. P., *Surgeon.*—Granted leave of absence for one month, with permission to apply for an extension of one month, on surgeon's certificate of disability.—*S. O. 181, Department of Missouri, September 8, 1882.*

HORTON, S. M., *Major and Surgeon.*—Granted one month's leave on surgeon's certificate of disability.—*S. O. 96, Department of the Platte, September 11, 1882.*

WRIGHT, J. P., *Surgeon.*—Granted one month's leave of absence, with permission to apply for extension of one month, on surgeon's certificate of disability.—*S. O. 181, Department of the Missouri, September 8, 1882.*

SMITH, ANDREW K., *Major and Surgeon.*—Leave of absence on surgeon's certificate of disability granted in special orders No. 131, August 22, 1882, Department of Arizona, extended two months, on surgeon's certificate of disability.—*S. O. 214, A. G. O., September 14, 1882.*

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

ORIGINAL LECTURES.

THE BACILLUS TUBERCULOSIS.

A Lecture delivered, by invitation, on September 18, before the College of Physicians of Philadelphia.

BY JAMES T. WHITTAKER, M.D.,

PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE IN THE MEDICAL COLLEGE OF OHIO, CINCINNATI.

(Reported for THE MEDICAL NEWS.)

OUR definite knowledge regarding tuberculosis dates from the day when experiments were first made to prove the specificness of the disease. We all remember well what a kind of thrill went round the medical world when Villemin, in 1865, first announced that he could inoculate the disease by means of tuberculous virus. We recall, too, the numbers of experiments which were performed at once with conclusions, some in confirmation, some in refutation, of his views. Chief among the opponents of them at this time was Cohnheim, who, with many others, stoutly maintained that he could produce the disease by the inoculation of other kinds of matter, even with wholly innocuous and inorganic matters, like elder pith, India rubber, etc.; in short, with anything that would produce irritation and caseation, which latter process came to be looked upon as a *sine quâ non*. Hereupon followed the doctrine of caseous pneumonia, a process secondary to catarrhal or croupous pneumonia in a vulnerable subject, and the sequence was catarrhal pneumonia, caseous pneumonia, phthisis. But the pathologists soon saw that neither catarrhal nor croupous pneumonia was wont to result in caseous pneumonia, and that, while phthisis was a disease so common as to carry off one-third of the productive population, neither of the so-considered causative affections occurred in sufficient frequency. Buhl then described a desquamative pneumonia, a form different from any other, whose business it was, as it were, to result in caseous degeneration. The pathology of tuberculosis now became involved in the hazy mists of clinical speculation.

The next direct observations were made in the experiments of Tappeiner, who saw that dogs, which naturally enjoy great immunity, became tuberculous when forced to breathe enclosed in boxes containing atomized tuberculous matter. These simple and striking experiments were variously repeated again with contradictory results. But the idea of specificness was thus launched again, and very soon thereafter when the oculists began to produce the disease by the inoculation of tuberculous virus in an organ where the whole process of development could be seen by reason of the translucency of its structure, the bulk of evidence was in favor of regarding tuberculosis as a specific disease. Cohnheim and Salomonsen now published the results of their inoculation experiments upon various animals, arriving at the conclusion that tuberculosis could be produced in no other way than by the introduction of tuberculous matter. Not the presence of giant-cells, the formula ran, not the process of caseation characteristic of disease, but solely the capability of inoculation. Thus there was gradually evolved the fact of the specificness of the disease, so that by the beginning of this year the doctrine had deepened into a general conviction.

Then so soon as this prime factor was acknowledged, the idea was naturally awakened, or rather reawakened, of the presence of a *contagium vivum*. Klebs, who is always first in this field, in point of time at least, described the actively-moving *monos tubercolosium* (bacterium). Schüller and Toussaint followed with micrococci, and Aufrecht followed them with two forms, one for scrofula, one for phthisis, one a micrococcus and one a bacillus. There was no satisfaction in these discoveries, which rested simply upon microscopic appearances, and they soon took their place silently among the list of the lost. By the beginning of this year Cohnheim was still able to say, "The principle of the infection in tubercular affections still remains a problem unsolved."

How Koch solved this problem is a matter of history already in the short time which has elapsed between April 10th, the date of his first publication, and the present day. He had already made fame in an obscure country town with his researches upon surgical infection, erysipelas, and milzbrand. But his reputation was chiefly confined to his co-workers, whose attention soon became fixed upon him on account of the accuracy of his observations and the precision of his statements. The recurrence of a particular form of bacillus under the same conditions of investigations concerning tuberculosis soon convinced him that he had something more to deal with than a mere accident or coincidence. The same means were at hand which had been adopted with such success in isolating the bacilli of milzbrand, and the principle of the solid culture soil was modified to secure the development of the bacillus tuberculosis. In this way he soon arrived at the conclusion that he had to deal with a special form of parasite, and the question only was as to its exact relationship to the disease. But first let us speak of the anatomy or morphology of the new discovery.

The bacillus tuberculosis is rod-shaped, hence its name, varies in length from $\frac{1}{1200}$ to $\frac{1}{3600}$ inch, is *absolutely motionless*, produces spores, 2-4, in the body, and is blunt at both ends. It is present in greatest abundance where the disease is in most rapid progress, and may be absent where the disease has ceased to spread. It is found in the interior of the so-called giant-cells, which are in reality but capsules for it, like the capsules of trichina.

But no one, certainly not Koch, would claim to differentiate a bacillus by its gross physical appearance. Milzbrand is easily distinguished from tuberculosis by the fact that its bacilli are pointed at each end, while the bacillus tuberculosis is rounded or blunt; but such differences are of value only when both bacilli are present for comparison. The spirochates of recurrens are distinguished at a glance, because they are spiral and not straight—because they are, in fact, not bacilli (rods) at all. The bacilli of mouse septicæmia are distinguished at a glance because of their extreme minuteness, and the bacilli of rabbit septicæmia are distinguished, because they are more like bacteria than bacilli, that is, they are more elliptic than linear. But these distinctions are of value only in the mycological laboratory, where they all occur with equal frequency, and would not interest us as clinical practitioners. So far as concerns morphology alone, the various bacilli are at the first glance very much alike, often so much alike as to be indistinguishable; but in this respect they are not unlike many other microscopic structures, say the spermatozoids,

which are apparently very much alike, and yet are very different.

But if the bacilli do not differ much to coarse inspection, so to speak, do not differ much in their anatomy, they do differ widely in their chemistry, which brings us to speak at once of the color tests; for the action of the coloring matters upon the bacilli is an expression of their chemical affinities. And here we find very great differences among the different bacilli. Pretty much all the micrococci can be tinted of any color indiscriminately, blue or red or brown, etc., but the bacilli show marked preferences for, or perhaps only become visible with, the use of certain hues. In the case of the bacillus of tuberculosis, for instance, the specimen supposed to contain it must be first tinted, then decolorized and tinted again, to bring it out with definiteness and distinctness. The bacilli of lepra, which closely resemble those of tuberculosis, can be colored only when fresh, not after desiccation; but hardened in alcohol they may be colored for years with gentian-violet or fuchsin. The spirochates of recurrens can be colored properly only in blood, but not in the tissues, with fuchsin, methyl-violet, or gentian. In section they can be colored only with aniline-brown.

I may best serve the purpose of my invitation here, I think, if I confine myself as closely as possible to the text presented, the bacillus tuberculosis, and I construe the occasion to mean a demonstration rather than a declamation. I have therefore had drawn merely as a means of coarse comparison the various sketches of micro-organisms of which I have spoken, and which I now exhibit, and having shown them, proceed to the clinical demonstration of the bacillus tuberculosis in the sputum.

This specimen of sputum, which answers to the old classical description *sputum rotundum fundum petendum*, I picked up in the hospital, or rather it was kindly given to me by an interne, Dr. Devlin, as taken from the cup of an advanced case. I have already prepared a specimen from it which I have here, and I proceed to repeat every step of the process necessary to its exhibition before you, commencing with the raw material. I select a small fragment of the sputum, and spread it with a knife as thin as possible over pretty much the whole surface of a cover-glass. The next step is to fix it, for if we should accidentally omit to fix it, we should have the albumen precipitated in forms which would puzzle the most profound mycologist. We may fix it, if we please, with glycerine-brown, a solution of analine-brown in glycerine, and for photographic purposes this is the best procedure, but for ordinary quick demonstration we fix it best by heat. I pass it therefore, two or three times through the Bunsen's jet, specimen side up, of course, taking care not to hold it in the flame lest it be burned up. The specimen is now fixed; it is dry, as any one may see, but it is not burned.

I have here now upon the table all the crude materials for the manufacture of the color-tests in common use. First is the bottle of aniline oil, a dark amber-colored fluid, and next is methyl-violet, which we select because it gives us the quickest results. The aniline oil mixed with distilled water, and allowed to stand four or five hours at least, with occasional agitation, gives us this soapy-looking fluid, which is labelled "the aqueous solution of aniline oil." The methyl-violet powder dissolved in alcohol, gives us this concentrated alcoholic solution of methyl-violet, and these two solutions mixed, in the proportion of one hundred grammes of the first to eleven grammes of the second, give us this deep violet, in thin layers iridescent, fluid which constitutes what we might call the first color. Several watch glasses having been half-filled with the first color, we let fall upon the surface of each, taking care that each rests upon, and does not sink below, the surface, a cover-glass with the specimen of sputum. We select several specimens because we might fail to find the bacillus in any one. Here now the specimens rest for half an hour, while we take up another portion of our subject.

Let us suppose that we will find in our preparation some specimens of the bacillus tuberculosis, or at least take it for granted that we can find it in most specimens of phthisical sputum, or in sections of tubercular structure; and on this subject there is now no doubt; the question at once arises as to the significance of the bacillus. The bacillus need not necessarily be the cause of the disease, any more than any one of the numerous micro-organisms found in the stools need be the cause of typhoid fever. In other words, presence does not imply pathogenesis. Koch might have felt convinced that he had found in this bacillus the cause of tuberculosis, but he would not be able to convince others to that effect unless he could produce tuberculosis with the bacillus. And that is what he did. But he had at first to isolate the bacillus from everything else. Koch had already effected this isolation of individual germs in other diseases, notably in milzbrand and forms of septicæmia, and he at once undertook to grow the bacillus upon the same soils. He soon found, however, that the bacillus would not grow, or would not grow well enough, upon any of these culture substances, and then he commenced to prepare for it its own native soil, the soil to which it is indigenous, so to speak, viz., blood. One might almost consider this thought as an inspiration of genius if it were not so strictly common-sense. The problem was, then, not to get a solid substance out of blood, for any one could do that in the process of coagulation, but to get a substance that would keep and would be clear. Sterilization and solidification at the same time were the factors sought. With the patience of science, he worked this problem out. Having drawn fresh blood into a perfectly clean vessel, he allowed it to stand absolutely at rest for twelve hours, when he withdrew into glass pipettes, previously sterilized by heat, the supernatant serum, and let it fall into test-tubes likewise purified and closed with plugs of sterilized cotton. These tubes were now subjected to a temperature of 58° C., one hour a day for six days, when full sterilization is effected, as proved by the fact that the blood will keep for months or years if the plug be not removed. Then solidification is effected by raising the temperature to 65° C., always in a water-bath, of course, withdrawing the tube from time to time to observe the period of gelatinization. Thus prepared, the tubes are inclined sideways somewhat, to offer a larger surface simply, and the bacilli, best from a tuberculous deposit in an animal artificially inoculated with the disease, are inserted upon the surface of the prepared blood. In other words, the seed is sown. For a week nothing is observed. At the end of ten days, however, a scaly appearance begins to show itself, the scale as it grows lifting itself from the subjacent soil and curling up upon itself like an old epidermis cell. It is very friable and is very easily detached, in which regard it differs widely from other micro-organisms, from milzbrand, for instance, which goes down into the substance of the soil as a film or cloud and gradually invades the whole mass. This scale upon the surface of the blood is the tuberculosis itself. A fragment of it put under the microscope is seen to be composed wholly of bacilli. It may be dissolved in fresh glycerine and injected, or it may be inserted with a needle or platinum wire and thus inoculation is effected. The wound heals in a day, leaving no trace, but in about two weeks the nearest lymphatic gland enlarges; in a few days more other

glands are affected and the animal begins to emaciate; in short, to present the general signs of tuberculosis. Now it may be allowed to die of the disease or it may be killed at any time and examined, when the organs present the picture of tuberculosis in degree corresponding to the amount injected. All these things have been so faithfully rendered before that I do not dwell upon them save to remark that while some animals, notably the dog and the rat, enjoy comparative immunity against spontaneous tuberculosis, there is no immunity to the artificial disease.

But this very fact of immunity and liability is an argument for the specificness of the disease. Thus the minute bacilli of mouse septicæmia kill house-mice but not field-mice. The bacilli of milzbrand kill mice, but not rats. The bacteria of rabbit septicæmia are always quickly fatal to rabbits and mice, and may be communicated to sparrows and doves, but do not affect guinea-pigs and rats. Age plays the *rôle* in these experiments, for which we are prepared by clinical observations concerning the acute infections. Thus milzbrand will affect young dogs and rats, but not older animals. Perhaps the most singular action in this connection is observed in mouse septicæmia, the bacilli of which kill young rabbits, but produce only a local affection or inflammation, a kind of erysipelas, in old rabbits.

We proceed now with our experiment. We observe, as we lift the cover-glass from its methylene bath, that the preparation is deeply stained. We shake off the superfluous color and immerse the specimen in the decolorizing solution, which consists of nitric acid (German pharmacopœia) one part to distilled water two parts, by volume. Moved about in this fluid, the color quickly disappears. Held between the eye and the light, the specimen looks almost colorless; but in washing off the superfluous acid, under a small stream of distilled water, it is seen that a faint tinge of color returns. The specimen is now ready for the second color, the concentrated aqueous solution of vesuvin, which colors all the field brown. One drop of the recently filtered, but still quite thick, solution is let fall upon the cover-glass while it is tipped about to diffuse it over the whole field, the cover-glass is pressed upon the slide, and the examination for bacilli commences. As we have already a preparation showing them in this specimen, we need waste no time in looking for them now..

Having said something of the color and the culture, let us pass now to the subject of control. No one would expect to cure a case of any disease by a mere knowledge of its cause. This is of course the prime factor, and is alone worth all the rest. But our knowledge of the bacillus tuberculosis is still too new for any consideration of agents destructive to the parasite. Nor is it probable that any such agent will be discovered, or will be ultimately necessary. We do not know any agent destructive to the trichina spiralis in the body, and yet the discovery of the trichina has almost put an end to the disease. That is, it has limited it to the ignorant and the careless. He who studies disease from the standpoint of control has a much wider range of intellectual vision than he who looks upon it simply from the standpoint of the common idea of a cure, But the bacillus tuberculosis from the standpoint of control must first be universally acknowledged.

It comes to us then with some points characteristic of it in its morphology, or we might say its anatomy; secondly, it has more definite chemical properties, as shown in its behavior to the aniline dyes; thirdly, it grows only upon a definite soil, different from many other bacilli, hence it has, we might say, speaking of it as of any other vegetable, its own agricultural properties; fourthly, it grows in its own peculiar way; and lastly, supremely important in a differential point of view, it has its own specific, exclusive, physiological properties, as evidenced by the constancy of its action upon pretty much the whole animal kingdom. Is there any other factor in all etiology that comes with stronger credentials? Let him explain it who can, however, the singular psychologic fact remains that every one is willing to admit all things in the case of milzbrand, but not in the case of tuberculosis. Is it, perhaps, because milzbrand so seldom affects mankind?

Koch never rushed into print with his discovery. He studied the bacillus tuberculosis thoroughly before he published the existence of it, and he determined the parasitic nature of it in the very simplest way: by the observation, namely, that it lives only at a temperature between 30° and 40° C. Milzbrand, its congener in so many ways, lives and produces spores in the coldest countries, and we see the worst epidemics of it in Siberia and other lands of the north. But milzbrand is not a parasite in the true sense of the term. The bacillus of milzbrand gets into the body of animals only accidentally, makes a little excursion, the Germans say, when it leaves the field, to be swallowed into the body of a cow. But the bacillus of tuberculosis requires body heat to live and thrive in, and produces no spores even two degrees above or below its natural climate.

So the bacillus tuberculosis is a true parasite, and when we recognize this fact, we almost get possession of it. It is like tracing a wild beast to its lair. The bacillus tuberculosis is not wild. It is motionless, sluggish mostly in its growth, but it is all the more cruel on account of these facts. Desiccation does not kill it, if it be kept sufficiently warm. Koch inoculated guinea-pigs with parasites from desiccated sputum a month old, and nevertheless produced the disease. One of the best of our own mycologists put it well when he said that "the mud of the gutter to-day is the dust of the air to-morrow." It is the sputum which disseminates the disease. In spontaneous tuberculosis the disease always begins in the lungs. Even in cases of basilar meningitis, a careful search will turn out nearly always a caseous bronchial gland as the initial lesion or depot whence is the local or general invasion of the body.

So here we have the clue to the control of the disease, and when the phthisical patient pulls out his sputum-saturated handkerchief, he opens the box of Pandora on the public highways. If I had to make practical response to the query what is the means of absolute control, I would say, in the light of existing knowledge, fire, and fire alone. No kind of bacillus will live in the fire. But a patient with phthisis cannot sit and spit in the fire. In the laboratory at Berlin there are many poisons floating in the air. The air of one of the rooms once became so permeated with milzbrand bacilli that a mouse, which is exquisitely sensitive to it, could not live in it more than twenty-four to forty-eight hours. Yet all the tools and instruments are thoroughly disinfected, that is, freed from germs, by the hot air- or water-bath; or, better still, when adoptable, by the Bunsen's jet. But the glass slides and cover-glasses could not be treated in this way. So there stands upon the table in each room a large glass vessel, holding half a gallon at least, and that much concentrated sulphuric acid is poured into each. Into this vat is thrown every slide and cover and test-tube that has been used, and once a month it is all cleaned out. Perhaps phthisical patients who may not be isolated as yet, as are other cases of a less malignant malady, might be restrained from disseminating the disease by the use of similar smaller portable vessels. But, however it be accomplished, the prime point now in prophylaxis is the recognition of the fact that it is the sputum which chiefly conveys the disease by contaminating our com-

mon reservoir of air. Just now it occurs to me, under the inspiration of this occasion, what many a classical scholar no doubt has thought of here without such stimulus: the disgrace it used to be held to be in the days of ancient Rome for a man to expectorate in public. And with our knowledge of the danger which lurks in the sputum often, how much graver insult it is than a mere breach of propriety, how much deeper offence than a mere disgrace.

COMPLETE OUTWARD DISLOCATION OF THE RADIUS AND ULNA AT THE ELBOW.

BY A. B. ISHAM, M.D.,
OF CINCINNATI, OHIO.

ON the 11th of June, 1882, J. W. F., an insurance solicitor, was at a livery stable, standing at the head of a horse, upon the left side, with the bit-reins grasped in his right hand. The animal gave a sudden rear and spring, throwing Mr. F. forward and sideways with considerable force upon his left side. The gentleman, in his endeavors to get up, then fell head foremost down a hatchway, a height of about eight feet, alighting upon his head and shoulders in a pile of saw-dust. The result of the series of movements was a dislocation outwards of the radius, and outwards and backwards of the ulna. In consequence I was summoned to attend him at his residence, which I reached shortly after the accident, and where I found present Dr. H. T. Lowry, the family physician. The luxation, I should say, was complete. The forearm was somewhat flexed and pronated, and was freely movable at the elbow. The depression in the head of the radius could be plainly felt, and the bone could be rotated on the ulna external to the humeral articulation. The coronoid process of the ulna rested upon the posterior surface of the external condyle of the humerus, with the olecranon process projecting upwards and backwards, entirely external to the olecranon depression into which the finger could be placed. The sigmoid cavity could also be felt just above and internal to the head of the radius. The skin was so tightly stretched over the internal condyle that it seemed as though it must break through, while transversely the joint appeared nearly double its normal breadth. This great breadth, together with the increase in the antero-posterior dimensions of the joint upon the radial side, and the pointed and thinned appearance upon the ulnar side, gave to the elbow a most singular aspect of deformity. It suggested the idea of fracture of the lower end of the humerus with dislocation and twisting outwards of the radius and ulna.

Reduction was accomplished without anæsthetics. Dr. Lowry held the humerus firm, while with one hand I seized the forearm, making movements of extension and flexion, and at the same time with the other hand exerting strong pressure upon the head of the radius and upper part of the ulna from without inwards. After a little rather vigorous manipulation in this way we had the satisfaction of bringing the bones back into their natural positions. Having assured ourselves of the correct apposition of the parts, the limb was fixed in a state of semi-flexion upon an angular wooden splint.

Dr. Lowry had subsequent charge of the case. The splint was kept upon the limb for four days. Of course, after such injury to the joint structures there was considerable inflammation and soreness. The patient, who was very squeamish about the matter of physical pain, would not permit passive movements of extension and flexion to be made, and in such slight movements as he made himself he was very careful not to pass the point of comfort, consequently some adhesions formed, and the arm remains very slightly flexed. He can flex it perfectly, pronation and supination are not interfered with, but he cannot make complete extension of the forearm, although it comes out nearly straight. He is enabled to use it for nearly all purposes that he could before, and in time exercise will undoubtedly extend it thoroughly, though extension might be had at once if he possessed the courage to submit to the moderate amount of effort necessary to break down the slight adhesions.

The position of the coronoid process upon the posterior aspect of the external condyle affords a basis for the opinion that, in this particular instance, the dislocation of the radius and ulna outward first took place in a backward direction. In regard to the mechanism, it is probable that the displacement was brought about by the left arm being thrown out extended, in advance of the falling body, in order to abate the severity of the blow. The palm of the hand, coming in contact with the floor, formed the point for the distribution of the force, which, in its transmission upwards first ruptured the anterior and posterior ligaments, permitting the radius and ulna to be dislocated backwards. The burden of the shock then falling upon the lateral ligaments, these gave way, and the force now being displayed obliquely outwards as regards the long axis of the radius and ulna toward the elbow-joint, the upper ends of these bones were carried external to the lower extremity of the humerus. The first fall is thus likely responsible for all the displacements, although it is possible that only the backward dislocation proceeded from it, while the lateral may have happened from the descent down the hatchway. As to whether or not it was a complete dislocation, depends upon the views one holds as to what constitutes a complete outward dislocation. It could hardly have been more complete without the joint had been wrenched asunder, making a compound luxation. The fibrous investments having given way, the muscles and other soft tissues, already overstrained and compromised, could have scarcely resisted any further tension.

While I looked upon it as an unusual form of injury, no authorities were consulted, and my attention was not drawn to its rarity until Dr. Sieber's report of his case of outward dislocation of the radius and ulna appeared in THE MEDICAL NEWS of August 19, 1882. The complete cases recorded are not numerous, and some of these might have been rendered much more complete by more careful description. Dr. F. H. Hamilton in the 6th and last edition of his work on *Fractures and Dislocations*,

has references to six cases of complete outward dislocation of both forearm bones at the elbow, which he says are all that have occurred in America up to the time of the revision of his book. He has overlooked the cases of Drs. D. Johnston, of Louisville, and J. E. Mears, of Philadelphia; while probably the revision was completed before Dr. W. Ekwurzel, of Philadelphia, reported his case. In all, with my own case, 11 cases have been published up to this time in the United States. The list is appended, that any one who desires it may establish their authenticity:

FOREIGN BODIES IN THE ANTERIOR CHAMBER OF THE EYE.

BY J. SANTOS FERNANDEZ, M.D.,
OF HAVANA.
(*Translated by* A. B. DE LUNA, M.D., of New York.)

FOREIGN bodies in the anterior chamber of the eye are not as frequent as the exposed position of the organ would lead us to suppose. I refer, of course, to substances penetrating into the anterior chamber and occasioning at the time no other lesion than the slight and almost imperceptible solution of continuity of the cornea. A. Tvert[1] speaking of wounds of, and foreign bodies in, the eye-ball, says that the records are few of what may properly be called "foreign bodies in the anterior chamber," and adds that amongst 5,465 patients seen by him in one year (1875), and of whom 342 were classified as "injuries," not a single case was found of the nature under consideration. In Galezowski's clinic I saw only one case during a period of seven consecutive months; while in my own, one is all I can find among the records of 10,000 cases. Desmarres mentions them as exceptional cases, a statement I would not gainsay, inasmuch as the statistics of my clinic, covering 12,000 cases of eye diseases, and a period of seven years, show only the three instances which I proceed to relate.

CASE I.—T. G., a mulatto, æt. 45 years, of good constitution, and by occupation a farm hand, was admitted August 14, 1875. Three days previously, while at work breaking stones, something hit him in the eye, the pain at the moment being so intense that he fell on the ground. On rising, the left eye felt very badly, could not bear the light, and ever since has been the seat, at night, of pain which extends to the superciliary region of the same side. On examination slight hyperæmia of the ocular conjunctiva was found, and three foreign bodies could be seen in the anterior chamber; two of them very small, and none larger than the head of an ordinary pin. Their whitish color strengthened the suspicion that they were fragments of stone. They were lying horizontally across the inferior hemisphere, in the angle between the iris and cornea, and very close to one another. The next question was as to the manner of extraction. A linear section of the superior portion of the cornea and seizure of the fragments from above with the iridectomy forceps is easy enough to plan, but in carrying it out there is danger of injuring the iris, lens, or cornea, without accomplishing the object. On the other hand, sections of the inferior portion of the cornea, in the region corresponding to the location of the foreign bodies, was also dangerous without iridectomy. The latter then was accordingly performed; but the knife had scarcely been withdrawn, when hypæmia occurred, and the foreign bodies were lost to view. Section of the iris now became imperative to insure the certainty of dragging them out; when effected, however, they were not to be seen, being concealed probably by the blood covering the ocular conjunctiva. A cataract dressing was applied and the patient put to bed, where he remained quietly, suffering no pain through the night, and when the dressing was changed the following morning, there was perfect union of the wound. Two days later hardly any vestige of hypæmia remained, and at the end of the week he was discharged, cured.

CASE II.—E. M., a Spaniard, 25 years old, and a workman in the Arsenal, was admitted July 13, 1877, and stated that three days before, while working on steel, a fragment hit him in the right eye, causing pain at the time, and a dimness of vision since then. Simple inspection by oblique light revealed a dark foreign body in the anterior chamber, located towards the inferior portion of the periphery of the iris and cornea. In size it was half a line in thickness by one in length, seemed somewhat adherent to the iris, and the aqueous humor was more opaque at the surface than in the rest of the anterior chamber. An opaque spot on the cornea opposite the foreign body indicated its point of entrance. The operation had to be postponed forty-eight hours, during which period the instillation of atropia was kept up. On the 15th, chloroform was administered, and I proceeded to extract the body by iridectomy at the region of its site, the fragment emerging entangled in the section of iris removed. The dressing already mentioned was applied, and the patient taken to bed. The pain incidental to the operation remained for several hours, diminished considerably during the night, and disappeared by the following morning. Everything then was doing well, and nothing untoward occurring, he was discharged three

[1] Recueil de Ophthalmogie, April, 1877.

days after. On the 27th of July and 6th of August, he reported in good condition, and with perfect binocular vision.

CASE III.—E. G. C., a native of Havana, 17 years old, and by occupation a mechanic, came to the clinic the first time on the 18th of July, 1877, on account of a speck of iron which got into his eye while at work only a few hours before, disabling him from further labor. On examination a foreign body resembling the point of a pin was discovered in the centre of the cornea and removed in the usual way. On the 27th of June, 1881, he once more made his appearance, complaining of something which had again lodged in one of his eyes. Placed in a good light a glistening foreign body could be seen lying on the iris, and which at times seemed located in the cornea. On this membrane no evidence of the passage of the foreign body could be detected at first, but a more searching inspection by oblique artificial light revealed a very minute opacity in the internal inferior segment, and almost at the level of the transverse diameter. This was the point of entrance, although the fragment lay in the internal and superior segment of the iris, the divergence being due to its flight from below upwards, in which direction it entered the eye. No change had taken place in the organ; the aqueous humor was still clear; the pupil reacted normally; and the only subjective symptom present was slight discomfort in the eye. The diagnosis established, the gravity of the prognosis was obvious, unless the foreign body could be skilfully extracted, and its removal was indicated before the occurrence of inflammatory action rendered it more difficult or impossible. On the afternoon of the same day the patient was anæsthetized with chloroform and the operation undertaken, the pupil being well contracted by the previous instillation of a few drops of bromohydrate of eserine. With a triangular knife a linear section half a centimetre long was made in the internal and superior segment of the cornea. The slow withdrawal of the knife was followed by the escape of the aqueous humor without prolapse of the iris, and the disappearance of the anterior chamber. Mathieu's iridectomy forceps were now introduced, and the foreign body seized, but so insecurely that it slipped off; a second attempt, however, was more successful, and it was safely extracted. After the operation atropia was dropped in the eye, and the patient vomited. No pain was complained of when the effect of the chloroform had entirely disappeared; the ocular conjunctiva was slightly injected; the pupil had dilated transversely, assuming an elliptic form; and on that portion of the iris where the fragment rested there was a slight reddish spot, probably an insignificant hypæmia. The patient seemed perfectly well on the following day, and was discharged at his own request.

The foregoing cases demonstrate in my estimation the course to be pursued when foreign bodies lodge in the anterior chamber of the eye, as well as the difficulties attending their removal, and the disorders that the delay in effecting this may provoke. Thus, in Case I., we see how the low position of the fragments was a serious obstacle to the operation, as the corneal section had to be performed in the very segment occupied by them, and there was danger of dragging the foreign bodies with the knife. The external or internal hyperæmia occurring in two of the cases cannot always be prevented, and so darkens the field of operation and conceals the foreign body as to necessitate the unavoidable mutilation of the iris by iridectomy. In the second case the operation was delayed, and incipient inflammatory action already gave warning of a possible iritis, exudation, concealment of the foreign body, and a difficult operation. The extraction of the foreign body, however, is always indicated; it is the *cause* of the trouble, and no principle is better established in medicine as that of the *removal of the causes* of disease. In a case of extraction of a foreign body with iridectomy, which I witnessed in Paris, the eye was so shrunken as to convey the impression of incipient atrophy of the bulb, and yet, after the operation, the organ regained its normal fulness, and I doubt not sight was restored. When, on the other hand, the condition of things is such as obtained in Case III., and the foreign body lies within easy reach of the forceps, and no hyperæmia supervenes, the operation presents no difficulties, and is crowned by complete success.

HAVANA, July, 1882.

AN AUTOMATIC CURRENT INTERRUPTER.

BY ROBERT MEADE SMITH, M. D.,
DEMONSTRATOR OF PHYSIOLOGY, UNIVERSITY OF PENNSYLVANIA.

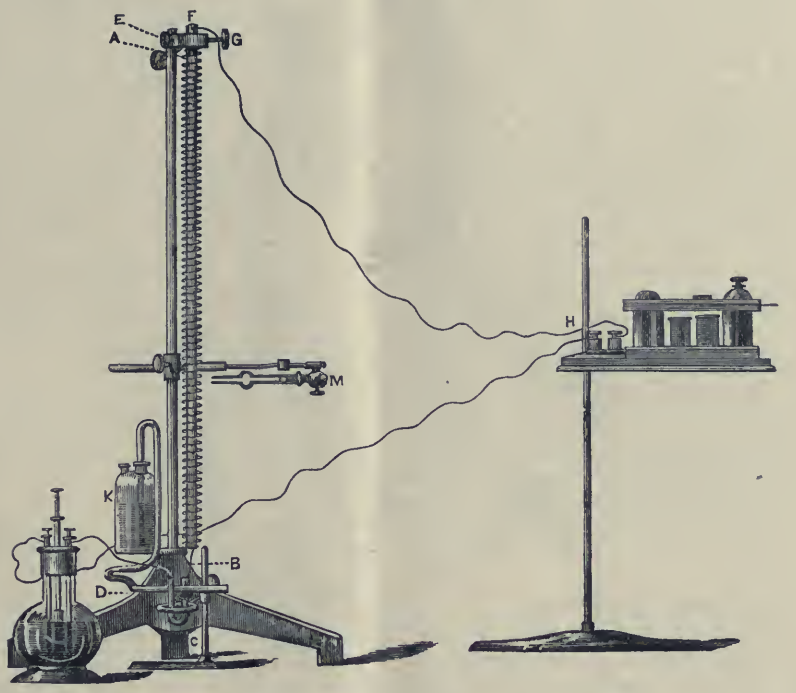
IT is well known that, according to the laws of Ampère, parallel electric currents passing through conductors in the same direction, attract each other, and an instrument based on this fact, known to teachers of physics as Roget's spiral, suggested to me that the same principle might be made use of for the automatic interruption of a current for various physiological or medical purposes.

The arrangement I have made use of is represented in Fig. 1. A spiral of insulated copper wire (made by wrapping the wire around a wooden cylinder) is suspended vertically from the cross arm A, so that the free end, B, dips into the mercury in the U-tube, C, in the other arm of which dips a second wire, D, connected with the + pole of a single Grenet cell. In the figure, the end, B, of the spiral should have been vertical, and the U-tube should have been more elevated. The fixed end of the spiral is connected at the binding-screw E with a second insulated copper wire wrapped in the same direction around the core of soft iron F, starting from its fixed end to its free extremity, and then returning, after having again wrapped around the core, to the binding-post G. The post G and the — pole of the battery are then connected with wires to the electro-magnet at H, or to any apparatus through which it is desired to send the interrupted current.

When now the zinc is pushed down into the battery fluid, the current passes through the mercury into the free end of the spiral, through the spiral into the binding-post E; then down the inner coil around the bar of soft iron and back to the screw G, then to the electro-magnet and back to the battery. As

soon, however, as the current commences to pass through the spiral, each coil is attracted by the one next above it, in accordance with the law of Ampère above alluded to, and the spiral shortens enough to draw its free end out of the mercury, thus interrupting the circuit; the coil then lengthens from its own weight, dips again into the mercury, shortens, breaks the circuit, falls again, and so on indefinitely. At K is a flask, containing alcohol, which is connected by a siphon to the U-tube; by flowing over the mercury the alcohol serves to keep its surface clean.

FIG. 1.



The value of the inner helix and core is greatly to intensify the attractive influence between the coils of the outer spiral; in the first place, the currents in the inner and outer spirals being parallel and in the same direction, attract one another; and in the second place, the current passing around the core renders it magnetic by resolving the Ampèrian currents into a current flowing in the same direction as that in the inducing helix, and intensifies its action, thus producing an action analagous to that resulting when the north pole of a magnet is brought within the coil of the north pole of a solenoid. For if a bar of soft iron, or the north pole of a bar magnet is brought partly within the coils of a solenoid (at its north pole, in the case of the magnet), the bar will be drawn still further within the coils of the solenoid until the magnetic forces are in equilibrium. But if the bar is fixed and the helix is free to move, as in the case of the apparatus described, the coils will be compressed and tend to cover the bar by an analogous action.

A similar intensifying effect on the outer spiral, though weaker than in the above instance, may be produced by inserting a permanent bar magnet, instead of the electro-magnet, within the coils of the spiral, the effect being due to the attractions between the Ampèrian current of the magnet and the helix, though it must be remembered that the *north pole* of the magnet must be downwards if the helix is dextrorsal, or the reverse, if it is a sinistrorsal helix.

By means of this apparatus interruptions of an electric current can be obtained at perfectly regular intervals, the rate depending on the length and coefficient of elasticity of the spring. If we have a spiral spring of uniform elasticity, one end fixed and one end free to vibrate, its rate of vibration will be governed by the same laws as those regulating the longitudinal vibration of rods fixed at one end, *i. e.*, the rate of vibration will be inversely proportional to the length of the spring, or half the spring will vibrate twice as fast as the whole spring, one-third three times as fast, and so on. Practically, however, we find that the elasticity will vary in different parts of the spiral from lack of uniformity in the wire, and from the fact that each coil, as we ascend the spiral, is supporting the gradually increasing weight of the coils below, and therefore the tension will vary in different parts of the coil.

It is a very simple matter, however, to determine once for all the rates of vibration of any given spring by ascertaining the number of interruptions for each coil by comparison with some given standard, when a scale can be made for future use.

Thus in the spring which I have most used, the entire length of spiral (consisting of 93 coils) vi-

FIG. 2.

One and a half interruptions per second.

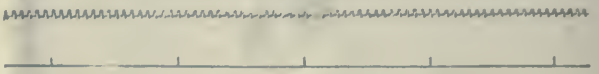
FIG. 3.

Three interruptions per second.

FIG. 4.

Ten interruptions per second.

FIG. 5.



Sixteen interruptions per second.

brates at the rate of 1½ per second; half the coil, or 46½ turns, should then vibrate three times a second. Practically we find that 43 coils vibrating, give this rate, and so on, with a slight discrepancy between the theoretical and practical numbers from the causes above alluded to. The coil is shortened to the desired length by means of the sliding clamp M.

A few examples (Figs. 2, 3, 4, and 5, acurately reproduced from tracings) are given to show the regularity of the rate of vibration; the lower line, which serves as a standard, was made by an electro-magnetic marker connected with Ludwig's current breaker (Unterbrechungsuhr) beating seconds. Tracings were made for each individual coil of the spiral and each tracing continued for thirty seconds, so as to avoid any errors in the omission of fractions where only a few seconds were counted; this also was done in the examples given, the reduction in length of the published tracings made being for the sake of economy of space. With this spiral, perfectly regular interruptions may be obtained varying from 1½ per second up to 16 per second, with the intermediate fractions.

MEDICAL PROGRESS.

CYST OF THE PANCREAS; LAPAROTOMY; DEATH.—BUKOWSKI relates in the *Centralb. f. Chirurgie*, No. 26, 1882, the case of a woman, aged 36, who was admitted into the Maria Theresa Hospital at Vienna with a fluctuating tumor, situated below the navel, and which could be readily depressed by the hand into the cavity of the pelvis. The tumor had then been present for two years and nine months, and was gradually increasing in size. It was diagnosed as an ovarian cyst, and on Feb. 27, M. Rokitansky undertook its extirpation. An incision twenty-four centimetres long was made in the linea alba, and a quantity of ascitic fluid allowed to escape. The tumor then protruded, and was found to be adherent on its anterior surface to the greater omentum, the posterior wall of the stomach, and the ascending and descending colon: the latter was torn in the attempt to free it from its adhesions, and the rent closed with five sutures. No less than fifty ligatures were necessary to control the hemorrhage. At the moment of attaching the mesentery, the cyst ruptured, and part of its contents escaped into the abdominal cavity; nevertheless, five litres of a brownish liquid were drawn from the cyst.

After two hours of fruitless attempts, it was necessary, on account of impending death, to abandon the idea of extirpating the cyst, the portions still adherent being divided with an ecraseur. The peritoneal cavity was washed out through a drainage-tube by two per cent. solution of carbolic acid. On the sixth day after the operation, feces escaped through the drainage-tube; on the next day the woman died.

At the autopsy, purulent peritonitis was found; the base of the cyst was connected with the tail and body of the pancreas, its interior being in connection with the pancreatic duct.

The fluid contained coloring matter, blood, serum albumen, serum globulin, paralbumen, cholesterin, and inorganic salts.—*Gaz. Méd. de Paris*, August 26, 1882.

INJECTIONS OF IODINE IN OVARIAN CYSTS.—M. BOINÉT read a paper on this subject before a recent meeting of the Societé de Chirurgie. His conclusions are:

1. That injections of iodine are especially efficacious in unilocular, limpid, serous cysts.
2. When the contained fluid is thick, tenacious, and albuminous, it is better to have recourse to ovariotomy.
3. Injections of iodine are also suitable to purulent cysts and hæmatoma.
4. When the cyst contains a fluid as clear as water, a simple puncture is usually all that is necessary for a cure; should the secretion again form, injections of iodine may be employed.—*Rev. de Thérapeutique*, September 1, 1881.

TEST FOR ATROPIA AND DATURIA.—If a specimen of either atropia or daturia, or of their salts, be covered with a little fuming nitric acid, evaporated to dryness on the water-bath, and when cold moistened with a drop of a solution of caustic potassium in absolute alcohol, a violet color is at once produced, which soon passes into a fine red. The violet color only is characteristic, since strychnia, when similarly treated, gives the red. According to *Zeit. f. Anal. Chem.*, one-millionth of a gramme of atropia sulphate can be thus detected. None of the other alkaloids act similarly.—*Chicago Med. Rev.*, September 15, 1882.

SEMPER'S METHOD OF MAKING ANATOMICAL PREPARATIONS.—DR. SEMPER, Professor of Zoölogy at the University of Würzburg, has discovered a method of making anatomical preparations which assures the preservation of the several organs. He has used the method constantly for several years, and the results are said to be excellent. After the dissection is made, it is macerated from one to five days according to its proportions in weak chromic acid (1 to 2 per 100); it is then washed, and treated with weak alcohol (30 per 100), adding alcohol of gradually increased strength. The preparation is then placed in strong alcohol from one to seven or eight days, afterwards in absolute alcohol, and finally it is left to macerate in turpentine until it is thoroughly soaked. The preparation is then spread out and allowed to dry by contact with the air, it thus becomes perfectly white; the different organs can be colored by using the best oil colors. When the preparations have been thoroughly dried after their maceration in turpentine, they reassume to a great extent their natural coloring, if they be immersed in a mixture composed of equal parts of a saturated solution of white sugar and glycerine.—*British Medical Journal*, September 9, 1882.

The Iodoform Treatment of Wounds.—In the Augusta Hospital at Berlin, for some time past, a 10 per cent. solution of iodoform in collodium has been used for the purpose of closing antiseptically small recent wounds, which neither required nor admitted of the application of a compress-dressing. The wound is first cleaned and disinfected, any bleeding stopped, and the necessary sutures applied, and then the surface is painted with the iodoform solution till a strong and perfectly protective covering is formed. This treatment is employed in the case of wounds healing by first intention, as well as in recently sutured large wounds to which, either on account of their position or as the result of operation, a compressing antiseptic bandage cannot be applied, *e. g.*, after excision of the submaxilla, or of small tumors, atheromatous cysts, or lipomata in the region of the anus, female genitals, or eye. The stitches remain in for eight or ten days, at the end of which period primary union is found to be complete. Dr. Theodor Görges (*Centralb. f. Chirurg.*) also had good success with this solution in the treatment of tracheotomy wounds during diphtheria. Instead of using the pad of carbolized oil lint which was formerly placed over such wounds, he now paints the raw surfaces (after hemorrhage has been arrested) with the iodoform-collodium. The application is repeated daily after the old crust has been first removed. The wound thus treated is merely covered with a small dry pad to keep off the pressure of the canula. This treatment has been employed in 25 cases altogether (22 diphtheritic) without the wound in any one case becoming phlegmonous, whilst under the old employment one out of every five cases would become so involved. In conclusion, he adds a few remarks on iodoform treatment in general. Since Professor Küster commenced the general employment of iodoform in the Augusta Hospital three months ago, the results obtained have been very different from the success so copiously announced from all sides. Not only have toxæmic symptoms been observed even after its employment in minute doses; not only have several cases of cerebral complication with typhous symptoms occurred; but erysipelas and phlegmonous inflammation have appeared in rapid sequence—accidents which, under Lister's treatment, have been there of the greatest rarity. Thus, among certain mammary amputations, where iodoform was applied under a typical Lister's dressing, three cases of erysipelas occurred, and one of these ended fatally. Suppuration also followed its use in cases of herniotomy and amputation of the upper arm, etc. Thus iodoform seems to afford but a slight protection against erysipelas, and even when applied in the finest powder to sutured wounds, which should heal by first intention, it seems to act as a foreign body and to lead to retention of secretion or aseptic suppuration. At all events, these accidents have induced them to return to the Listerian treatment, under which, during the past year, were obtained such speedy and satisfactory results. Perhaps these remarks may call forth a clearer definition of the cases in which iodoform should be chosen, and of those in which the earlier forms of treatment should be relied on.—*Edinburgh Medical Journal*, September, 1882.

Chloroform-water.—In an article in the *Gazette des Hôpitaux*, of March 25, attention is drawn to this highly useful preparation of chloroform for internal use. Profs. Lasègue and Regnauld have shown that the solubility of chloroform in water does not exceed 9 per 1000. The solution is obtained by pouring an excess of chloroform in a bottle three parts full of distilled water, shaking the mixture repeatedly, and then allowing the insoluble chloroform to deposit until complete transparency is obtained. The separation of the saturated solution is then made by decantation, or by means of a siphon. This solution, being too strong for internal use, requires dilution. (The *Aqua chloroformi* of the British Pharmacopœia has a nominal strength of 1 in 200.) Various salts (as chlorate of potash, borate, bicarbonate, and salicylate of sodium) may be dissolved in this water without undergoing any modification; and Profs. Lasègue and Regnauld are of the opinion that chloroform-water, either pure or diluted, will meet every need in the internal administration of this substance. Having a pleasant taste in the mouth which lasts for a minute or two, it is well calculated to disguise the unpleasant taste of various medicines, as castor-oil, etc. By the direct action which it exerts on the mucous membranes, it may prove useful in certain affections of the mouth, gums, teeth, velum, and pharynx. It exerts a stimulant action on the stomach, but it acts differently according as it is taken before, during, or after a meal, and according to the lapse of time that has intervened between taking the meal and the absorption of the chloroform. Given before a repast, in aid of the appetite, the chloroform-water is a bad agent; but given after a meal, whether alone or combined with an alcoholic wine and sweetened, it increases the stimulant properties of the wine or produces like effects. When administered to allay the manifold troubles which supervene during the course of digestion and produce its disturbance it has much value. Its maximum therapeutic action is obtained three or four hours after the meal, when functional disturbances show themselves by yawning, distention, gaseous eructations, a sense of epigastric pressure or heaviness, flushings of the face, and threatenings of vertigo. But when the digestive disturbances are manifested by acute lancinating pains of the stomach, oppression, palpitations of the heart, fleeting febrile action, dryness of the mouth, painful tympanites, etc., the action of the chloroform-water is injurious; this stage contra-indicates all forms of stimulants. In a word, the chloroform-water acts on the stomach in the same calming way as upon the interior of the mouth, and if it does not cure the affection, at least it mitigates its consequences. It is a remedy for the crisis, but does not render needless the proper treatment-in-chief. It is eminently suitable in painful digestion arising from dilatation of the stomach.—*Practitioner*, September, 1882.

Rare Form of Senile Gangrene.—Mr. Joseph Bell reports the following case: W. H., æt. 75, a very healthy, temperate, contented old man, of spare habit and fairly healthy arteries, was sent into the hospital on January 17, 1882. The second toe of his right foot was black and evidently dead. He said that a few days before admission he had met with an accident, the iron plate of a retort having fallen on his foot. The whole foot was red and swollen; not much pain, and no constitutional disturbance. On January 24th, the dead toe was nipped off with scissors, no blood being lost; the tendons alone required division. The bones were noticed to be curiously macerated, as if they had lain long in water. In another fortnight the third toe, which had been alive and healthy, except for a slight redness, also died and was lifted off, the bones being macerated, and this time the tendons also destroyed. The resulting gap left by the removal of these two toes was large but painless, and suppurated freely with little odor. Up to March 10th, all went well, and the wound was nearly healed. The extremities of the second and third metatarsals had separated from their shafts at the epiphysial junction, and were lifted out with ease.

On March 10th, however, without either pain or elevation of temperature, a dark blush was noticed all

over the great toe, which had hitherto looked healthy, and half way up its metatarsal bone. The circulation in this area was exceedingly sluggish, the finger leaving a white dimple on pressure, which took several seconds to refill with blood. After two or three days of doubt a bulla was noticed to form just on the dorsum of the metatarso-phalangeal joint. This bulla rapidly raised the cuticle to the size of a florin, and, being cautiously cut into, showed the true skin, not as usual in such cases, either shrivelled up or sloughing, but as if it had melted into a shreddy pultaceous mass, and this involved not only skin, but cellular tissue, ligaments, and periosteum, for by March 20th, without any displacement of parts, suppuration, or odor, the proximal phalanx and metatarsal head were both exposed as if thoroughly macerated, and lay loose in this pultaceous mass. The edges of the ulcer or cavity were everted and undermined as if by a gumma, were of a pinky redness. but exhibited no granulations or any attempt at repair. Having watched many cases of senile gangrene from embolism also for months under careful observation, he was quite familiar with the usual processes of separation, whether moist or dry; but he had never seen or read of any case in the least resembling this one, whether in its rapidity of maceration of tissue, its curious cessations or intermissions, its freedom from pain, and apparently trifling effect on the constitution.

The treatment was purely expectant, no intereference that could be avoided, absolute rest in bed, milk, diet, which was well borne, and locally keeping the limb at an equable temperature by cotton wadding (carbolized) and marine lint to sop up discharges.

The result has been remarkable. To-day, June 30th, the apparently dead and macerating heads of metatarsal and first phalanx have recovered themselves, granulations have formed, and now the wound has closed, with the exception of a line of granulations about a quarter of an inch long and one-sixth of an inch broad, under which can be felt a thin scale of carious bone. The old man is quite well, and goes home this week.—*Edinburgh Med. Journ.*, August, 1882.

INTESTINAL OCCLUSION BY AN ABSCESS OF THE PANCREAS; LAPAROTOMY; DEATH.—At the last Congress of German Surgeons, ROSENBACH related the case of a woman, aged 57 years, who, for eight weeks before her entrance into the hospital, had been suffering from obstinate constipation. When she came under Rosenbach's care, she had not had a movement of the bowels for three days, and was suffering from stercoraceous vomiting. The left half of the abdomen was greatly distended with gas, and a fluctuating tumor, the size of a child's head, could be felt below and behind the stomach. As the constipation could not be overcome, laparotomy was performed, the abdomen being opened by an incision in the linea alba over the tumor. The tumor was surrounded by an inflammatory zone, and could not be isolated; it was accidentally ruptured, and a fetid liquid escaped. The edges of the sac were united with the edges of the abdominal wound, and drainage carried on through tubes. The patient died of collapse in six hours. The autopsy showed that the case was one of abscess of the pancreas, extending to the stomach and lesser omentum, and originating in a point of necrosis of the pancreas. It had contracted adhesions with the large intestine, and had obliterated its canal by compression.—*Gaz. Méd. de Paris*, August 26, 1882.

THE INFLUENCE OF NERVE-SECTION ON THE FORMATION OF CALLUS IN FRACTURES.—From an elaborate experimental investigation, DR. W. KUSMIN draws the following conclusions:

1. After section of nerves in cases of fracture, the formation of callus is much greater and firmer than where no such operation has been performed.

2. The lime impregnation of the callus, after nerve-section, proceeds more rapidly, and terminates in genuine bone formation.

3. The formation of bone in the callus first occurs by metaplasis.

4. In the later stages the bone is formed in a manner analagous to endochrondal ossification; that is, neoplasis is associated with metaplasis.

5. The first signs of ossification in adjusted fractures commence under the periosteum and at the outer periphery of the old bone. In preparations in which the nerves have been divided, the process progresses much more rapidly in both localities.—*All. Wiener Med. Zeit.*, August 29, 1882.

AN ABNORMALLY LONG STYLOID PROCESS AS THE CAUSE OF DYSPHAGIA.—DR. WIENLECHER relates two cases of the above trouble. In the first, a lady patient experienced since twelve days a severe pain, accompanied by a sensation of pressure in the right tonsil. On examination, a hard body was found, the blunt end of which pressed forward against the mucous membrane. It could be traced outwards, could not be felt above, but corresponded in all to the site, etc., of the styloid process. Dr. Wienlecher pressed it forcibly outward and it disappeared with a crash, plainly heard by all around. The dysphagia disappeared. After ten months the patient returned with the same trouble which had appeared since three days. Pathology and treatment were the same, neither after the operation nor on the next day could a hard body be felt. In another case observed by the author it was impossible to fracture the bone. The author draws attention to the fact that this anomaly may impede incision of the tonsil from below upward.—*Chicago Med. Rev.*, September 15, 1882.

IODOFORM IN TERTIARY SYPHILIS.—DR. THOMANN, of Gratz, concludes a communication on this subject, as follows:

1. Iodoform exerts a favorable influence on the process of healing of tertiary syphilitic lesions.

2. Very large doses can be borne, and hasten a cure.

3. Iodine can be found in the urine for as long as 43 days after the cessation of the administration of iodoform; the organism, therefore, is for a long time subjected to the action of the drug.

4. No unpleasant effects are produced, the acne and coryza which often follow prolonged administration of iodide of potassium can be therefore avoided.—*Centralb. f. d. Med. Wissen.*, September 2, 1882.

TREATMENT OF VAGINITIS.—For the last two years M. GOUGUENHEIM (*Journ. de Méd. de Paris*) has treated acute blennorrhagic vaginitis at the Lourcine by a method which has given him most favorable results, and which is exceedingly simple. It consists in placing in the vagina, with the aid of a small speculum, bags of variable size made of coarse muslin, and nearly filled with a powder composed of a mixture of nine parts of alum and one part of tannic acid. The bag is left *in situ* from twelve to eighteen hours, and is then withdrawn, while the patient is in a bath, by means of a cord attached to it, as to an ordinary plug. After the withdrawal of the bag, the vagina is syringed out with warm water to facilitate the removal of the membrane that has formed. After a few repetitions of this mode of treatment, twice a week, the discharge ceases. Dr. Gouguenheim says he has borrowed the idea of these bags from the practice of Madame Lachapelle.—*Dublin Journ. of Med. Science*, July, 1882.

Nystagmus and Hemeralopia of Miners.—At the meeting of the French Association for the Advancement of the Sciences, on August 24, 1882, M. Dransart read a paper on this subject, based on ninety-three observations. The following are his conclusions:

1. The nystagmus of miners depends upon a paresis of the elevator apparatus of the eyes, both muscles and nerves, produced by excessive fatigue. This paresis is independent of any central lesion and any abnormal refraction. General atony, anæmia, and bad light are secondarily important factors, but are not essential to the production of the nystagmus.

2. A condition of hemeralopia, intimately associated with the nystagmus, also exists in miners; it can, however, occur independently of the latter affection.

3. The nystagmus is a curable disease; it should not be considered as exempting from military service.—*Gaz. Méd. de Paris*, September 2, 1882.

Diet in Chronic Nephritis.—Prof. Lichtheim (*Corres. f. Schweiz. Aerzte*, No. 7, 1882), in an address to the Medico-Chirurgical Society of Berne, treats this subject with much fulness. The ordinary practice, he says, is to prescribe a diet more than usually rich in albumen with a view of replacing the loss from the kidneys. The patient's danger from loss of albumen is, however, much less than that arising from the imperfect filtration performed by the kidneys, and the consequent retention of nitrogenous waste-products in the blood. For a considerable time this tendency to retention may be counteracted by the increased blood-pressure and cardiac hypertrophy, which effect a sufficient elimination even from the defective kidneys. This being the case, it must needs be unwise to strain this attempted compensation unduly by giving nitrogenous foods in quantity; this merely implies increased production of nitrogenous waste and increased work on the eliminating organs. The result of such a regimen must be a further increase of the blood-pressure and greater cardiac hypertrophy, until at last the heart ceases to respond and becomes dilated; in other words, a new difficulty to the embarrassed circulation is raised. By giving food which contained little nitrogen the author has found that the dyspnœa of confirmed nephritics rapidly disappeared. He is inclined to regard this dyspnœa not as uræmic, but as a simple consequence of insufficient contraction of the heart, analogous, therefore, to the dyspnœa of cardiac patients.—*Practitioner*, September, 1882.

The Normal Venous Pulse and the Venous Pulse in Pericardial Effusions.—From an experimental study of this subject, Dr. Frantz Riegel draws the following conclusions:

1. The normal jugular venous pulse of animals is anadicrotic, katamonocrotic. The anadicrotic wave corresponds with the diastole of the ventricle and the auricular systole, and the katacrotic limb with the ventricular systole. In these peculiarities it resembles the normal human venous pulse.

2. In high degrees of increased intra-pericardial pressure, as in pericardial exudation, the venous pulse is diastolic-presystolic, and never coincides with the systole of the ventricle.

3. Increase of intra-pericardial pressure depresses the arterial and elevates the venous blood pressure. On the other hand, in excessive intra-pericardial pressure the initial increase of venous blood pressure gradually disappears.

4. The normal collapse of the veins at each systole of the heart is caused by the synchronous diastole of the auricle; the increase of negative pressure in the pericardium at each ventricular systole, by decrease of volume, may also assist in the production of this phenomenon.—*Deutsches Arch. f. klin. Med.*, Bd. xxxi., 5 u. 6.

Resection of Carcinomatous Large Intestine.—Richter (*Centralb. für Chirurgie*) reports the case of a patient, aged 33, who had been frequently under treatment for stenosis of the intestines (said to be the result of dysentery) situated in the region of the sigmoid flexure, where a firm cord-like swelling could be felt through the abdominal walls. At length the patient's symptoms became so urgent that immediate operation was resolved on. The abdomen was opened in the linea alba, the distended small intestines, wrapped in disinfected cloths, were drawn to one side, and the stricture, seated a little above the sigmoid flexure, was exposed. The affected intestine, drawn well forwards, was divided by a transverse incision immediately above the point of stricture, and a large quantity of very offensive, tenacious, fluid fecal matter was evacuated; but in spite of this the distention of the small intestines was scarcely diminished. The gut was then punctured in several places with a trocar, the gas and feces expressed, and the punctures closed with catgut sutures. The portion of intestine which had been drawn forward was then disinfected and replaced *in situ* above the stricture. The lower end of the colon was kept closed during the operation by the fingers of an assistant. Three inches of the strictured portion of the gut were then excised, and the upper tube was joined to the lower by means of Czerny's suture. The short mesentery was treated in a similar manner. The point of union was then fixed opposite the inferior extremity of the wound in the parietes, which was left unsutured in its inferior fourth. Finally a Lister dressing was applied. Duration of the operation, three hours. On examination the stricture was found to be cancerous. A small stool was passed only a few hours after the operation; but on the eighth day, feces and flatus escaping through the wound, the Lister's dressing was abandoned and open treatment adopted. Gradually the stools began to pass *per vias naturales*, and by April 19th, or fifty-four days after the operation, the patient was able to spend the greater part of the day out of bed, although for a month more there was an evening rise of temperature. The fistula at last healed under applications of the thermo-cautery and argenti nitras. On October 19th the patient was dismissed strong and well.

Köhler considers that resection is preferable to colotomy in all cases where the disease has not extensively involved neighboring structures, or where the patient's strength is not so reduced that this severe operation cannot be safely performed. Von Erekelen's researches show that life was prolonged in 62 per cent. of the published cases of colotomy; but, of course, the focus of disease was not thereby removed, and there was no thought of a radical cure. Such a cure is, however, much more likely after extirpation, for the growth rarely infects the lymphatic glands, and is but little prone to metastatic formation or recurrence. Besides, this method renders the objectionable artificial anus unnecessary. Up to the present time 18 out of 25 cases of completed resection of the large intestine have taken a favorable course. In three of these the disease has recurred with a fatal result; but the remaining 15, *i. e.*, 60 per cent. of all those operated upon, seem to be perfectly cured.

As regards operative details, Köhler recommends that the abdominal incision be made in the linea alba, arrest of hemorrhage being thus facilitated and a good view of the parts obtained. During the operation the divided end of the intestine is to be kept closed by the hand of an assistant, whilst, if possible, the piece to be resected and the adjacent healthy part are drawn beyond the abdominal wall, so that an escape of intestinal con-

tents may not take place into the peritoneal cavity. Finally, he recommends that, as in the case above described, the sutured intestine should be fixed opposite the lower end of the wound in the abdomen (Köhler, *Inaug. Dis., Breslau*).—*Edinburgh Med. Journ.*, Aug. 1882.

Hystero-epilepsy in a Boy.—M. Bourneville has put on record, in the *Progrès Médical*, for August 26, a second case of hystero-epilepsy in a boy. The child was thirteen years of age when he came under observation. The following points in his history seem worthy of note: His parents were first cousins. His father was subject to migraine in early life; his mother had spasmodic wry-neck in infancy, one of her sisters was idiotic (?). The patient was the eldest child; he seems to have been always an excitable child and easily frightened, subject to night-terrors. His hysterical attacks commenced in the month of February, 1880, about a month before he came under observation. The first one came on, whilst he was at work at school, with vertigo, and, after lasting two hours, was terminated by singing, crying, and laughter. The senses of hearing, sight, taste, and smell were decidedly less acute on the left than on the right side, and the same may be said of the common sensibility of his buccal mucous membrane and conjunctiva. His intellectual faculties seemed unimpaired, and he was said to be gentle and affectionate. There was no history of masturbation. On examination, several different areas were found, over which pressure was painful (*zones hystérogênes*). They were situated as follows: 1. "*Clou hystérique*," at a small spot, two centimetres in front of the vertex. 2. "*Rachialgie*," over the spinous processes of the fifth, sixth, and seventh dorsal vertebræ. 3. Symmetrical spots on each side in the fifth intercostal space midway between the nipple and the axillary line. 4. A painful spot in the seventh left intercostal space, about five centimetres from the spot. 5. A spot over the manubrium sterni. 6. Symmetrical spots over the loins. 7. A spot almost over the centre of the iliac fossæ, corresponding to the "ovarian" region; that on the left side is the most marked. The attacks recurred at regular intervals, and lasted from one to two hours. They were preceded by an aura, which consisted of a sensation of a ball rising from the penis to the epigastrum, and thence to the level of the larynx. This was followed by the "*clou hystérique*," and then he lost consciousness. The attacks were characterized by a preliminary stage of rigidity of unusually short duration, succeeded by a clonic period, which was, on the other hand, of unusual length, comprising varied contortions and passional attitudes. During this period he would try, by different methods, to injure himself or those around him. The attack concluded, he sometimes had hallucinations of sight. He also presented a hemianæsthesia, at one time on the left side, at another on the right. The patient was cured (apparently in a permanent manner) by the assiduous use of cold douche-baths. The case may be noted as a typical one both of "hystero-epilepsy," and of the way in which the physician's office is magnified in such disorders by our French *confrères*.—*Med. Times and Gaz.*, Sept. 2, 1882.

Dystocia by Transverse Occlusion of the Uterus.—The following rare case is reported in *Le Praticien*. The woman, thirty-nine years of age, had borne a child eighteen years ago. When pregnant again after this time she had very severe labor pains, but without any effect. The examination showed a membrane separating the cavity of the uterus from the cervix, which latter was voluminous, and as large as a silver dollar. The posterior cul-de-sac of the vagina was pressed downward, which indicated a sac-like dilatation of the posterior segment of the uterus. The membrane was cut with scissors, but the cavity of the uterus could not be entered. The woman died three hours afterward. The autopsy showed a placenta prævia, the child already putrefied. The cavity of the uterus was separated from the cervix by a membrane, in a transverse direction, and three centimetres long.—*Chicago Medical Journal and Examiner*, August, 1882.

Oil of Eucalyptus in Midwifery Practice.—Dr. Samuel Sloan, Obstetric Physician to the Glasgow Maternity, recommends the use of the oil of eucalyptus in midwifery practice. He has found it to possess, as an antiseptic, the following advantages: 1. It is non-poisonous. 2. In the quantity and strength required it is unirritating. 3. It does not coagulate the lochia, which, by separating the lips of the vulva, can be seen to flow out in a liquid stream. 4. Its odor is, with rare exceptions, a pleasant one. 5. It seems to act as a uterine stimulant, causing and assisting to maintain uterine contraction. Formed into a pessary of a suitable shape and size it is easily applied to the neighborhood of the os, and retained there. To secure this, the pessary must be broad and short, must melt slowly but completely, and must contain a large percentage of the antiseptic oil. These requisites he has found the following formula to supply: Oil of eucalyptus, six drachms; white wax, four drachms; cocoa butter, four drachms; mix and divide into twelve pessaries. One of these must be applied night and morning immediately after the usual sponging, and, though the napkins are frequently changed, the odor will be quite perceptible on the one removed prior to the next sponging, twelve hours later. In cases of miscarriage, or when the lochia has diminished materially in quantity—say, six days after confinement—he has found the above strength produce irritation, and the following will then be found preferable: Oil of eucalyptus, four drachms; white wax, one hundred and sixty grains; cocoa butter, four drachms; divide this mixture into twelve pessaries, and label them No. 2. These may also be used at first night and morning, and afterwards at night only. These pessaries are made by first melting together the wax and cocoa butter in a vessel resting in hot water; the oil of eucalyptus is then mixed with this, and the fluid poured into the ordinary two-drachm pessary mould, each cavity being somewhat more than half filled. He has never been able to satisfy himself that the eucalyptus was absorbed into the system to any material extent. This is probable, however, and, in one case, seemed to be proved. This was a case of severely ruptured perineum, which was stitched and united throughout. The pessaries had been continued for sixteen days, when an erythematous rash appeared over the whole body, disappearing immediately on the cessation of the eucalyptic treatment. Though uncertain as to the fact of a material absorption of the oil into the system, he is persuaded that the oil does not remain at the os, but freely passes into the cavity of the uterus. For it is admitted that the uterus for several days after labor is naturally in an alternate state of contraction and relaxation, and whilst during contraction it will empty itself, during relaxation again whatever is lying at the os or upper part of the vagina will be sucked into the vacuum produced. The eucalyptus will therefore find its way quite into the uterine cavity. When he said that, with rare exceptions, the odor is agreeable, he referred to a decomposition of the eucalyptus oil which sometimes takes place, giving the napkin a semi-fetid odor. That this does not arise from a change in the lochia he has proved by simply omitting the next pessary when due; he then found that the lochia was absolutely sweet.—*Lancet*, September 2, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, SEPTEMBER 30, 1882.

THE MEDICAL DIPLOMA SCANDAL.

THE original medical colleges, which have been organized to supply a real want, alone have a right to existence. After the needs of the country have been satisfied, colleges go on organizing, not in obedience to any legitimate requirement, but merely to satisfy the ambition of professorial aspirants. Thus, for example, taking a certain area of country, which has Louisville for its geographical centre, we have in Cincinnati three regular medical schools, in Columbus two, in Cleveland two or three, in Toledo one preparing for business, in Fort Wayne two, in Indianapolis two, in St. Louis four, in Chicago four, in Louisville four, in Evansville one or two, in Nashville two or three, in Memphis one or two, and in Pittsburg the preparations are making for one. It cannot be pretended that such an array of medical schools is justified in any need of the medical profession. One each in Cincinnati, Louisville, Chicago, and St. Louis, would amply supply every demand. In the smaller cities, the lack of a suitable clinical field, and of other facilities for teaching medicine and surgery, should operate to correct the ambition of medical college makers.

There is, however, usually in these smaller cities one leading doctor who organizes a faculty from the material of the town, or of the neighborhood, an old warehouse is converted into a college building, and clinics chiefly surgical, and made up of the patients of the surgeon, are commenced, with the intention to advertise the great man as their real object. When one medical school is organized, a second must follow. A faculty created from the adherents of one or two great men, does not provide for the remaining "medical talent" of the town, and hence great dissatisfaction is felt. Very soon a new organization is arranged, and the "just claims to recognition" of the hitherto-unrecognized professors are suitably acknowledged. In some instances the city or town having but two or three sufficiently eminent men for the practical chairs, an anatomist, or physiologist, or professor of some other scientific department, is summoned from some distant city. Then the pretence for organizing a new college, is the recognition of "home talent." What motive soever may be alleged for founding the college, the real intention is to obtain the title of Professor, and the supposed privileges and benefits thereunto belonging. Unfortunately, the title becomes cheap, sometimes actually goes a begging in the smaller cities with three or more colleges, for presently the distinction consists in not being a *professor*. Indeed we know of one city, where it is usual in the eulogistic funeral discourses, to say of the eminent deceased, he had been frequently importuned to accept this or that chair in the medical colleges, but had invariably declined.

Amongst the newly-made professors, dissensions are apt to arise. The one great man of the school must be deferred to, and the professors must vie with each other in their efforts to enhance his glory.

Then, again, the great men suppose that they must rise or fall with the fortunes of their institutions; when they are surrounded by medical schools, having an equally energetic purpose to live and flourish, the nature of the struggle can be readily understood. We learn of shifts to make students, of personal solicitations to induce students to enter the school, of honors promised to practitioners to secure their influence over expecting and actual students, and of other practices that touch, it seems to us, on the lowest point of professional degradation. In this heartless struggle, without any principle, the professors, we doubt not, try to do their duty with the inefficient and inadequate means in their hands. As is usual, when they learn of the evil methods by which their school is kept up, some one rebels, and then discussion and disruption follow.

The present scene of conflict is the Columbus Medical College. The history of the existing medical convulsion will serve to illustrate the nature of the others. If the present case did not involve some questions of high importance to the medical profession, we would be little disposed to give it prominence by recognition and discussion.

In the present controversy we learn from the pamphlets that have been published that Dr. Baldwin, then a professor in the school, opposed the

conferring by the Columbus Medical College of the degree of M.D. on a man who was graduated in a month after he matriculated, and whose antecedents were of an unsavory character. Dr. Baldwin united with Dr. Reeves, of West Virginia, in the exposure of these iniquitous practices. Dr. Hamilton, of the Columbus School, denounces Dr. Baldwin for his share in these laudable attempts to correct flagrant abuses. Every right-minded member of the medical profession looks on such exhibitions with unfeigned regret. Divested of all extraneous questions, such is the status of this controversy, and although there have been ample time and opportunity, we regret to say that the authorities of the Columbus Medical College have failed to offer any satisfactory explanation of their action in the case under discussion, and the profession is therefore able to reach but one conclusion.

PECULIAR PARALYSIS OF THE BRACHIAL PLEXUS.

IN 1874 Erb communicated to the Congress of Naturalists assembled at Heidbelberg, the details of four cases in which a peculiar paralysis of the brachial plexus had occurred. The peculiarities consisted in the distribution of the paralysis, and the localization of the lesion. Muscles innervated by very different branches of the plexus were simultaneously affected. The muscles paralyzed were the deltoid, the biceps, the coraco-brachialis, and the supinator longus, which are innervated by filaments from the circumflex, the musculo-cutaneous, and the musculo-spiral. E. Remak, some time afterward, submitted a precisely similar case to the Berlin Medical Society, and recently Hoedemaker has published several new observations. To these German examples are now added two French cases published by Lannois.

The paralysis has usually come on after exposure to cold, and corresponds closely in its etiologic relations to some kinds of facial paralysis. The localization of the paralysis is the point of difficulty. Erb found that there is a place in the brachial plexus near the scaleni where the motor filaments above referred to, unite. In subjects properly trained, the necessary dexterity having been acquired by practice, these filaments may be excited by a fine electrode at a point between the two heads of the scaleni, where the fifth and sixth nerves emerge, causing movements of the deltoid, biceps, coraco-brachialis, and supinators only. Remak, in his case, placed an electrode at the outer border of the transverse process of the sixth cervical vertebra, on the healthy side, and caused, with a mild current, a contraction of the supinator longus, and with a stronger current, a simultaneous contraction of the deltoid, biceps, and coraco-brachialis in addition. An application of the same current strength, on the paralyzed side, caused no movement. The electrical condition of the paralyzed muscles has been the same in all the cases—that is, the electro-contractility is lost.

In Lannois' cases, the most recent thus far reported, the same peculiar localization of the paralysis was observed, and the electro-contractility was also lost.

We may conclude, therefore, that this peculiar malady is a peripheral paralysis—a neuritis probably, of the fifth and sixth cervical nerves which unite with others to form the cervical plexus. The condition, in the cases of long standing, has not been modified by treatment, but the more recent examples have been less intractable and have improved under suitable galvanic treatment.

MISSIONARY PHYSICIANS.

We have recently received several publications relating to medical missions, which have interested us not a little.

Few persons now living can recall the beginning of the missionary enterprise in this country, at least, but the sending of medical missionaries is a matter of quite recent date. At least, so we thought until we were astonished to learn that the illustrious John Abercrombie founded the "Edinburgh Medical Missionary Society" so long ago as 1841. The rewards of successful practice are such that it seems strange at the first blush that any physician should leave bright prospects behind him, and banish himself voluntarily to Asian or African heathenism. That clergymen should do so seems but a natural outgrowth of their profession. But love to God, and the "enthusiasm of humanity" have led no less than one hundred missionary physicians to devote themselves to this self-denying work. These men, at least, cannot be accused of utilizing their kindness as a part of their "stock in trade."

The medical missionary has opened the door more than once to the preacher. Hearts that were closed to all intellectual appeals, became responsive to the glad tidings when brought to them by the physician. Indeed, it is but renewing the lesson of the Judean hills and valleys, for well-nigh all the recorded miracles were miracles of bodily healing. Moreover, it is but just that civilized nations should atone, in some small measure, for the ills they have inflicted on heathendom. Syphilis and whiskey are twin evils which—to our shame, be it said—most surely follow in the wake of our mercantile marine, and to these in China, at least, the curse of British opium must be added.

Such men have done more than merely practise medicine and act as missionaries. True, they have done this, and to no little extent. A neccessary part of their work is the dispensary and the hos-

pital. At Travancore Dr. Thompson reports twenty-five thousand patients in a year, and at Swatow, drawn from twelve hundred and twenty-one surrounding villages, Dr. Lyall has had as high as three hundred and fourteen in a day, his lowest number being forty-six.

But they have added also to our knowledge of the art and the science of medicine, to pathology, etiology, medical geography, materia medica, botany, geography, ethnology, and kindred sciences. Not to allude to older contributions, the late report of Dr. Turner, in the *Glasgow Medical Journal*, on one hundred and thirty-six operations for elephantiasis within seven years, not rarely three or four operations being done in one day, and with a result of only two deaths, is a noteworthy contribution to operative surgery, from Samoa. Dr. Berry, in Japan, is not only doing a vast work in practice and in teaching large numbers of native physicians, but is also attempting to work out the problem of the hygienic treatment of leprosy, and, with the assistance of the government, bids fair at least to limit and ameliorate, if not to extirpate, this loathsome disease. Dr. Palm, also in Japan, has entered upon a work of extreme importance in a nation so progressive yet so barbarous in their obstetric medicine. Under the auspices of the Edinburgh Society he has established a Nurse Training School with Miss Shaw, one of the "Nightingale probationers," from St. Thomas' Hospital, as his head nurse. A movement in this country, a few years ago, to establish such a training school in Japan unfortunately failed for want of due support. But the especial fitness of women for medical missionary work has been more largely appreciated in this country than in any other. Besides numerous women physicians already in the East, the earliest of whom were sent by American Methodists, there were last winter at the Woman's Hospital in this city eight women preparing to go as medical missionaries. Heathen women need such help even more than men, for they are excluded from the help of male physicians, and are victims of the profoundest superstition, ignorance, and cruelty.

All of this work, it must be remembered, is done practically alone. Help there is none within hundreds and sometimes even thousands of miles. We confess that to tackle an eighty pound tumor of the scrotum, with not a single trained assistant to give the ether, or to assist in controlling the hemorrhage, in the sponging, and the mechanical details, would not be entirely attractive. Yet Dr. Turner not only did it, but finished the operation in twelve minutes, and with results as flattering to his good judgment as to his operative dexterity. Indeed, the Edinburgh Society, of whose pupils he is one, only encourages young men of more than the average promise, and urges upon them the importance of acquiring a thorough education. Only men of the highest attainments, as well as the most unselfish devotion, are fitted for the work. This is in accordance with what might be supposed when we look at the names of the men at the head of the enterprise; Abercrombie, Simpson, Scoresby-Jackson, Spence, and Handyside, among the dead; and Grainger Stewart, William Turner, Alexander Simpson, Crum Brown, Patrick Heron Watson, Underhill, and Joseph Bell, among the living, represent the best talent of Edinburgh. The society keeps up a training school and dispensary, aids young men whose means are cramped, and also establishes hospitals and dispensaries abroad wherever most needed, It is entirely undenominational and assists all churches. It issues a neat "quarterly paper" at one shilling a year, in which all the latest medico-missionary news are published.

Any of our readers who desire to obtain further information as to its work, or to subscribe to its valuable paper, can do so by writing to Rev. John Lowe, F.R.C.S.E., 56 George Square, Edinburgh. Its extensive work demands large outlay, and we join with our British *confrères* in commending it heartily to the generosity of those interested in its objects. It graduates five students this year, but the appeals are triple the number of men ready to go.

SOME FUNCTIONAL VISUAL TROUBLES DUE TO CEREBRAL LESIONS.

GRAEFE maintained the view, which still prevails in Germany, that the only disorder of vision due to a mere cerebral lesion is hemianopsy—or loss of half of the visual field. This opinion is based on the semi-decussation of the optic nerve fibres in the chiasm. Charcot, however, demonstrated from clinical facts that a cerebral lesion may cause a sensory hemianæsthesia, accompanied by a sensorial anæsthesia with amblyopia, and that in cases of hysterical hemianæsthesia there may exist an unilateral functional disorder of the brain. At the time when Charcot maintained the existence of a crossed amblyopia as a consequence of a single lesion of the hemisphere, without any lesion of the corresponding optic bands, there had been no anatomical facts to disprove his assumption. Clinical observation, and the facts of pathological anatomy, are necessary to settle the question. Féré has collected seventy-four observations with which to examine the relation of the visual disturbances to cerebral lesions. His conclusions are embraced in the propositions given below:

The only visual disorder, heretofore observed in the hysterical cases of hemianæsthesia, is amblyopia with concentric narrowing of the visual field on

the same side as the disorders of cutaneous sensibility. In certain subjects of cerebral disease, as in the hysterical, the hemianæsthesia may be replaced by a hemidysæsthesia, accompanied by the same visual disorders. In subjects affected with such cerebral diseases as aphasia, hemiplegia, hemichorea, hemianæsthesia, etc., loss of half the visual field, or hemianopsia, is quite often encountered. Amblyopia of cerebral origin accompanies the disorders of cutaneous sensibility, whether of little, or of considerable extent. The anæsthesia or dysæsthesia may be limited to the tissues of the eye.

Cerebral amblyopia may present almost the same symptomatic relations as the hemianopsy. Nevertheless, although pure hemianopsy is frequently associated with aphasia, amblyopia is rarely thus connected, but is found in association with ordinary disorders of sensibility. Cerebral lesions may exist with a disorder of vision resulting from the combination of concentric narrowing of the visual field, and hemianopsy. This affection, which always accompanies other troubles of sensibility, appears to be determined by a lesion situated on the opposite side toward the sensory centre, in the optic tract, the tubercula quadrigemina, or the efferent fibres.

CREMATION.

The time is rapidly approaching when the problem of the disposal of the dead of our large cities must find some other solution than the cemetery. That cemeteries are noxious to health, and especially when they are on the banks of streams which furnish the water supply of the city, is a point that needs no argument. The advocates of cremation seemed at first more like enthusiasts with a "fad" in their heads; but as time has passed on, it would seem that they are slowly, but surely, winning at least a hearing, and after a time we believe they will win the day—and justly.

From the hygienic point of view, cremation is plainly the best way of disposing of the dead, and, as now conducted, it is done decorously, quickly, and cheaply. The *Pall Mall Gazette* states that in Milan two bodies can be cremated in an hour, the cost being from three to five dollars. The Siemens furnace at Dresden, which cost only $250, is still more quick in its action. There are several furnaces in France, in which the time of incineration ranges from one hour to two, and the cost from four to five dollars. The Kuborn apparatus is intended for the battle-field, and reduces twelve bodies at once in an hour and a half to an indistinguishable mass of gray ashes, so that a dozen of them could dispose of more than 2500 bodies in twenty-four hours. Prof. Gorini, of Lodi, professes completely to destroy a body in twenty minutes by immersing it in a hot solution believed to be chiefly chromic acid.

There are practically but two arguments against it. Sentiment, at least with the general public, is the chief one, and although that will long hold its own, especially while in this country the want of proper facilities makes cremation difficult, yet in the end it must yield. Health must be the first consideration, and the dead must yield to the living.

The other is a more serious one from a professional point of view, for cremation may easily destroy the evidences of poison. But exhumation has won few laurels in our courts of justice, so that we shall lose but little by the proposed change. Moreover, not a few mineral poisons can be readily detected in the ashes, which deprives the argument of at least a part of its force. In spite of its disadvantages, we believe that cremation is by far the best mode of disposal of the dead.

Why will not some enterprising cremationist set up a Siemens furnace in or near one of our large cities? The pecuniary risk would be small, and we have little doubt that, were cremation made easy, practicable, and cheap, it would be resorted to with increasing frequency, and far more than reimburse its proprietor.

ALBUMINURIA IN CONSUMPTION.

In a certain proportion of the cases of consumption, about six per cent., albuminuria appears as a complication. The importance of this symptom varies with the condition of the kidneys. In the simplest form, it is a mere temporary congestion; but a congestion due to blocking of the pulmonary vessels may after a time set up permanent changes in the renal structures. When permanent from the onset of the symptom, it may be a dyscrasic malady, due to tuberculosis of the kidney, or it may be produced by amyloid degeneration, which is a frequent complication of the suppurating processes of tuberculosis, the kidney being one of the organs attacked.

It is a fact of much interest that when albuminuria occurs, the fever process and the sweating cease, and thus an illusive appearance of improvement is induced. A subnormal temperature has been observed in some cases. When therefore, in phthisis, the usual daily febrile movement does not come on, the urine should be examined. It need hardly be observed that the prognosis will be distinctly affected by the discovery of a permanent albuminuria. When the quantity of albumen present in the urine is large, and the temperature even slightly subnormal, a rapid decline in strength and an early termination may be expected.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF VIRGINIA.

Thirteenth Annual Session, held at Fauquier White Sulphur Springs, September 13, 14, and 15, 1882.

(Specially reported for THE MEDICAL NEWS.)

(*Concluded from p. 361.*)

SEPTEMBER 14TH, SECOND DAY.—MORNING SESSION.

AFTER the reading of the minutes, which were approved, the vote was called for on the following resolution,

CONCERNING THE ELECTION OF OFFICERS,

presented yesterday by Dr. Joseph A. White, of Richmond:

"*Resolved*, That the officers be elected on the second day of each annual meeting; that they shall be chosen exclusively from among those attending the session, and that the President-elect shall make his appointments for the ensuing year before the session closes."

After a lengthy discussion, this resolution was laid on the table.

The committee apointed to express the sense of the Society in reference to the

NEW YORK CODE,

reported the following resolutions, which were unanimously adopted:

Resolved, That this Society views with concern and deep regret the action of so influential a body as the Medical Society of the State of New York at its last annual meeting, whereby an attempt is made to break down the barriers so wisely erected by the Code of Ethics adopted by the American Medical Association and subscribed to by this Society, between the practitioners of the science of medicine and quacks and charlatans, and desires to express in the most emphatic terms its disapproval and condemnation of that action.

Resolved, That we consider the Code of Ethics of the American Medical Association as the best guide we possess for the conduct of medical practitioners, and hereby reaffirm our adherence to it, and deprecate any change unless it shall be made by the American Medical Association, which body we regard as the representative of scientific medicine in this country.

Resolved, That we approve the action of the American Medical Association, whereby it refused to receive the delegates of the New York State Medical Society.

DR. JOSEPH A. WHITE, of Richmond, was then requested to present the

REPORT ON ADVANCES IN OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY.

He first considered the most recent advances as to the *histology* of the eye. Contrary to preconceived ideas, the cornea draws its nourishment from the scleral vessels, and discharges its waste products into the anterior chamber. He noted the pathology of sympathetic eye disease and the modes of its transmission into glaucoma, and the method of relief for its different forms, and the connection between intra-cranial disease and optic neuritis. He remarked upon the alarming increase of refractive troubles—especially myopia—in school children, as a subject of great importance. He referred to some necessary legislation regarding the appointment of color-blind engineers, pilots, etc.

Mydriatics were then taken up. For many years *atropia* has been the sheet-anchor of the oculist. Its chief danger consists in its use in glaucoma and in troubles secondary thereto. *Duboisia* does not dilate the pupil for nearly so long, and cases of glaucomatous symptoms following its use have been reported. In some persons it produces a species of intoxication. Its advantage is that it may be used where there is an idiosyncrasy regarding atropia. He has also used *sulphate of hyoscyamine* and *hydrobromate of homatropine*, especially in refractive troubles, and for ophthalmoscopic diagnosis.

Hyoscyamine (½ per cent. solution) paralyzes accommodation very quickly, and its effects pass off sooner than atropia or duboisia, yet it sometimes produces giddiness and a moderate intoxication. Homatropine is more evanescent in its effects upon accommodation. Thus far, he has seen no report of glaucomatous trouble following the use of either hyoscyamine or homatropine.

Myotics.—Formerly, calabar bean was the only one used. Now we have eserine and pilocarpine. *Eserine* acts more powerfully than pilocarpine. It is used locally in *acute* glaucoma, serpiginous ulcers of the cornea, serous iritis, episcleritis, etc.

Pilocarpine is used both locally and internally because of its stimulant and absorbent properties. All solutions of these drugs are best preserved by first boiling the solution, and then adding carbolic acid in the proportion of one-half grain to the fluidounce.

Iodoform is especially applicable to granular ophthalmia, trachomatous pannus, interstitial keratitis, etc. It has also been used in conjunctival tuberculosis, hypopyon, keratitis, and seems to diminish the purulent secretions.

Boracic acid is used in slight conjunctivitis, in the strength of one to four grains to the ounce of water. He cautioned his hearers against the common use of such astringents as nitrate of silver, lead solutions, etc.

The use of *antiseptics* he considered very troublesome and needless in the after-treatment of cataract. He advised the careful cleansing of the operating instruments and the operator's hands in alcohol.

Optico-ciliary neurotomy was then reviewed in brief. Dr. White insisted that if sensibility in the eyeball returns after the operation, then the eye must be taken out. In this connection he related the history of a case which was somewhat peculiar because of the amount of hemorrhage which followed the operation and continued for some time thereafter.

Turning his attention to *Otology*, he first spoke of *purulent diseases of the ear*. The best treatment is an antiseptic, combined or not with a mild astringent. Boracic acid with zinc oxide or alum forms a good local application; alum, however, is apt to increase the discharge if there is caries. Then apply a bit of absorbent cotton to exclude air, and keep the parts dry.

When *polypi* are present, alcohol, with or without boracic acid dissolved in it, makes the best application where an operation is not undertaken.

The intimate relationship of ear and throat troubles was remarked upon, and the importance of familiarity with the use of the rhinoscope, laryngoscope, etc., was impressed.

The paper was ordered to be published.

DISCUSSION.

In response to an invitation, DR. JOHN N. MACKENZIE, of Baltimore, Fraternal Delegate from the Medical and Chirurgical Faculty of Maryland, in referring to the report presented by Dr. White, said that the great difference of opinion which prevailed in regard to the cure of *throat consumption* arose from the confusion of two distinct forms of ulceration which are met with in the larynx of the consumptive. The classification into catarrhal and tubercular phthisis held here as in the lungs; and by making such a division, order would be restored to the conflicting opinions of authorities, and

a standpoint would be secured for a scientific solution of the various problems which the subject presented, and a guide to prognosis afforded of considerable value to the practical physician. The chronic ulcerative laryngitis of the tubercular patient differed from simple chronic laryngitis in its extreme chronicity, its tendency to relapse, and the frequent occurrence of ulceration which showed no disposition to cicatrize, and, which, if neglected, would eventuate in laryngeal phthisis, although proof of its culmination in tuberculosis was wanting. He believed that the vast majority of reported cases of so-called laryngeal tuberculosis could be referred to the category of catarrhal inflammations. The plan of treating this variety of laryngeal phthisis by thorough local cleansing and disinfection, followed by the direct application of iodoform and morphia to the ulcerated areas, had met with success in his hands; and he considered this method of grappling with the disease as one of the greatest advances which had been made in the control of this troublesome disease. The second form of ulceration—the true tubercular—was much more difficult to deal with; but the fact that pulmonary consumption was curable, the well-known cicatrization of the local lesions of tuberculosis of other organs, as the intestines, and the excellent results which had followed incisions and drainage of pulmonary cavities, would lead, *à priori*, to the possibility of similar success in the treatment of laryngeal phthisis. The laryngeal ulcer is the pathological analogue of the cavity in the lung, and it, therefore, seemed rational to assume, that what was true of the latter, would be equally applicable to the former, especially as in this case local treatment would be more effectually carried out. Dr. M. recommended the constant inhalation of medicated vapors as an adjunct to the treatment, and described the methods in general use. He also spoke of a device which he was in the habit of using—namely, the substitution of cotton pellets in the nose for the cumbersome respirators sold in the shops.

Passing then to the subject of *nasal catarrh*, Dr. Mackenzie warmly advocated its treatment by surgical methods, especially the removal of the hypertrophied tissues covering the turbinated bones, the excision of the pharyngeal, and, if necessary, the faucial tonsils, and he related cases in support of operative interference. As a substitute for surgical operations for the straightening, perforation, or fracture of the deflected septum, Dr. Mackenzie suggested the removal of one or more of the turbinated bones. He concluded his remarks by cordially thanking the society for its courteous invitation, and for the attention with which the members had listened to his crude ideas.

DR. WM. L. ROBINSON, of Danville, reported

A CASE OF EAR TROUBLE RELIEVED BY ELECTRICITY,

which elicited an interesting but very latitudinous discussion by several members.

THE EARLY DIAGNOSIS OF PHTHISIS PULMONALIS

was the title of a "volunteer paper" by PROF. M. L. JAMES, of the Medical College of Virginia, Richmond. He introduced his paper by referring to the fact, that four years ago he had presented a paper before the Society with the title, "The Question of the Curability of Consumption and its Treatment." In that paper he had shown from the opinions of eminent lights in medicine, from the facts of pathological anatomy and from his own experience that many cases of consumption were curable. He stated that in his own experience, however, the cases of cure were limited to two, after the disease had progressed to the establishment of cavities; the cavities in the two cases having been small ones, but that as many as twenty-three cases in his private practice, and of which he had kept careful records, had yielded to the force of remedies in earlier stages. Admitting that he was right in his opinions, Dr. James regarded the question of its early diagnosis as one of the weightiest in Medicine. He conceded that it was not always an easy diagnosis, but for that reason was the more important.

With a brief reference to the pathology of the disease, in which he said the weight of authority established the fact that there was at least a close alliance between true tuberculosis, and those chronic inflammations of the lungs which marked the earlier stages of pulmonary consumption, he proceeded to a review of the symptoms and physical signs which marked the earlier stages, in which he claimed that, while there was much of difference in the violence of the symptoms in different cases of the disease, from those overwhelming invasions which destroyed life in a few weeks, to such as were so feeble in their destructive force as to require years for the termination of their mortal work; still in all cases there was distinct evidence of profound constitutional disturbance, and it was practically important to recognize such variations. He laid much stress upon the presence of fever, which he said applied to all of the cases under his observation at some stages of the disease, though he said that so eminent an authority as Williams had said, that in a few cases it was absent, and sometimes the temperature was sub-normal. He said, however, that in this disease, more than in any other that he had observed attended by febrile phenomena, the exacerbations of the fever were variable, sometimes scarcely departing from the types of the intermittent and remittent forms of malarial fever, while in other cases it would sometimes be absent for several days, or occurring during the day in considerable elevation for so short a period as a half-hour. His description of the type of the fever was variability. He said that the proper recognition of the fever of phthisis could only be made by the thermometer, the surface temperature of the hands and face being entirely fallacious. He thought that every suspected case should be provided with a thermometer and the temperature taken several times in the twenty-four hours, and oftener than the physician in private practice could make observations himself.

He then proceeded to analyze the value of the several symptoms, referring to the presence of the *bacilli*, which Koch claimed would be found in the sputa in the suppurative stages, concluding that unless that could be accepted as established, there was no one pathagnomonic symptom or sign, and that that even was delayed beyond the stage when remedial measures were usually efficacious; but that there was in all cases such an assemblage of symptoms and signs as would justify a positively decisive diagnosis. These he believed to be an impairment of general health, varying much, but always profound, attended with more or less acceleration of the pulse, and febrile exacerbation, and emaciation, with physical signs, first indicating pulmonary congestion, and then consolidation, more or less circumscribed and complete, with at least occasional crepitant, subcrepitant or mucous râles, also more or less circumscribed; impaired expansibility of the lungs; all of which symptoms and signs have been more or less gradually developed, and which have existed for a period longer than two weeks, and have been anticipated by prodromic symptoms of greater or less marked distinctness.

The Committee on Nominations of

OFFICERS FOR THE ENSUING YEAR

presented the following nominations, each of which was confirmed by the Society:

Vice-Presidents: DRS. MEADE C. KEMPER, of Goshen; O. H. BAIRD, of Waverly; JOSEPH A. WHITE,

of Richmond; J. S. APPERSON, of Town House; GEO. B. JENNINGS, of Ruckersville, and J. W. DILLARD, of Lynchburg.

Recording Secretary and Treasurer, DR. LANDON B. EDWARDS, of Richmond.

Corresponding Secretary, DR. HUGH M. TAYLOR, of Richmond.

Chairman of Committee on Nominations, DR. LEWIS WHEAT, of Richmond.

The members of the Executive and Publication Committees, the same as last year.

ELECTION OF PRESIDENT

by ballot, resulted in favor of DR. WM. D. COOPER, of Morrisville, Fauquier County, Va. The retiring president, DR. G. WM. SEMPLE, was elected an

HONORARY FELLOW

of the Society.

Rockbridge Alum Springs, Va., was selected as the

PLACE FOR THE NEXT ANNUAL SESSION.

Time of meeting, either the last week in August or the first week in September, 1883.

AFTERNOON SESSION.

PATHOLOGY AND TREATMENT OF INFANTILE PNEUMONIA,

by DR. BEDFORD BROWN, of Alexandria, was the title of the first paper read, of which the following is an abstract. The lobar and catarrhal forms of pneumonia are the most frequent in infants under a half year of age. The râle of lobar pneumonia is rather coarser and more on the subcrepitant order, with less complete dulness on percussion than in adult pneumonia. Catarrhal pneumonia is the most common form in infants, as well as the most dangerous. The rapid secretion of mucus cuts off proper inhalation, and thus cyanosis occurs. He has seen cases threatened with fatal suffocation in twelve hours. The accumulation of carbonic acid in the blood produces a narcosis that reminds one of opium poisoning. The tendency of this carbonic acid poisoning is also to suppress cough.

The rate of respiration in infantile pneumonia is probably higher than in any other disease—even up to 100 per minute. The *character* of the respiration is therefore very short and quick, and the inhalations enter only a small portion of the air-cells. In the baby with extensive catarrhal pneumonia, the walls around the bases of the lungs do not expand normally, but the muscles of the apex of the chest and those of the back and neck are thrown into extraordinary activity.

The character of the cough.—In proportion to the extent and gravity of the lung disease the cough diminishes in frequency and force, and thus declines to aid expectoration. Such a condition needs artificial stimulation of the function of coughing. The agents used are antiseptic; they disinfect the accumulated matter in the bronchial tubes, and excite these tubes to action, and hence the expulsion of the offending cause. Dr. Brown uses, by spray apparatus, three or more times a day, this solution:

℞.—Alcohol,	℥j.
Water,	℥ij.
Carbolic acid,	℈ss.
Bicarbonate of sodium,	℥j.
Salicylic acid,	℥j.
Chloral hydrate,	℈ss.—M.

The atmosphere surrounding the head and chest as well should be charged with the spray whenever necessary to excite cough and expectoration. This has always, in his experience, excited cough and expectoration, with improvement in the breathing and complexion—at least for the time being, and in some cases he is sure he has thereby saved life.

Character and rate of pulse.—In bad cases the pulse runs up to 200, or even 225 per minute. These high figures of pulse and respiration are never reached in the adult. With this rapid and feeble pulse, each cardiac diastole is so brief and imperfect that very few drops of venous blood are received in the right side of the heart with each pulsation. Hence the tendency of the blood to accumulate in the venous system, producing cyanosis by carbonic acid poisoning, and narcosis, and other consequent effects. And yet patients have recovered even with a pulse of 200.

Treatment.—Digitalis is the best agent to slow the excitable and feeble heart in infantile pneumonia. It is not as rapid and dangerous as veratrum and aconite, but is just as efficient. Belladonna is a valuable adjuvant to the digitalis. It soothes the irritable condition of the sympathetic system. It also curtails superabundant secretion. This is markedly so in cases of catarrhal pneumonia; but belladonna does not suppress cough. The mild preparations of ammonia are particularly valuable in liquefying viscid mucus and hastening its expulsion. The wine of ipecac should never be dispensed with. It is a potent promoter of expectoration. Ipecac exerts an extended influence over the entire sympathetic and vaso-motor systems, and controls hemorrhage and regulates secretion. The combination of soda, potash, or ammonia with ipecac—especially with ammonia—constitutes the very best means of assisting the bronchial tubes to expel their contents. Opium, when moist râles are abundant, is inadmissible. In the use of opium we must be guided by the extent of tissue invaded. If extensive, opium must be discarded. Bromides are especially valuable applications for quieting nervous restlessness and for procuring sleep in the class of cases discussed. In lobar pneumonia, when the muco-fibrinous secretion is very tenacious, the iodides of potash and ammonium, spirits of ammonia, and ipecac are very serviceable.

DR. J. E. CHANCELLOR, of Charlottesville, reported in brief a case which endorsed the views expressed by Dr. Brown.

The *Ex-presidents* of the Society offered

PRIZES

of $50 for the best surgical essay prepared by any member, and $50 for the best medical essay.

The subject selected for the surgical prize was

RECENT PROGRESS IN ABDOMINAL SURGERY.

We make a synopsis of the essay which received this prize, presented by DR. HUGH M. TAYLOR, of Richmond, Va. His report embraced a review of the recent advances in ovariotomy, Battey's operation; extirpation of the uterus, spleen, and kidney; resection of the stomach, bladder, and intestines; operations for pelvic and abdominal tumors and abscesses; and last, but by no means least in importance, the writer thought, operative interference in intussusception, occlusion, and cancer of the intestines, and in gunshot and other wounds of the abdomen and abdominal viscera. Prominent among many who have contributed to the advance of abdominal surgery are mentioned, Tait, Thornton, Billroth, Keith, Wells, Sims, and Thomas. In ovariotomy we find the greatest triumphs in abdominal surgery, and to its successes and teaching is due the present activity in all peritoneal surgery. The writings of Keith, Tait, and Billroth, tend to disprove the value of Listerism in peritoneal surgery, while those of Wells, Thornton, Schroeder, and others of equal eminence, carry great weight in favor of its use. While not an advocate of Listerism, the writer was forced to recognize it as one of the open questions in surgery. The triad of Keith—care, cleanliness, and drainage, is, in the opinion of the writer, the embodiment of antiseptic abdominal sur-

gery. A wide distinction is drawn between Listerism and antiseptic surgery. The opinion that all good surgery is antiseptic surgery is concurred in. The writer reports two cases of ovariotomy, in which the value of drainage was clearly illustrated. The first was a suppurating dermoid cyst, which was so firmly attached to the right iliac fossa, that a large part of its base had to be left *in situ*. It presented a honeycombed, suppurating mass and suggested a hopeless prognosis. In spite of the unfavorable outlook, the patient recovered from the operation and went about the house for six or eight months. The unexpected prolongation of life was due to the fact that nature established two outlets for the pus, one along the pedicle and one into some part of the intestinal canal. The second case was an extensively adherent multilocular cyst, and the traumatic injury done in separating them warned the operators to provide for removal of the inflammatory products. This was accomplished by passing a tube through Douglas's cul-du-sac. For the first five or six days, about a pint of bloody serum was drained through the tube each day; the patient continued, however, to do well until by accident the tube was pulled out. Immediately before this accident the prognosis was favorable. Immediately afterwards the temperature and pulse went up and the patient showed the distended belly, restless delirium, anxious expression, vomiting, hiccup, and all of the symptoms which note the beginning of the end. Drainage, the writer thinks, is indicated whenever any raw surface is left in the peritoneal cavity, as no one can foretell the amount of inflammatory products which circumstances unfavorable to repair may make the most trivial wound discharge. The danger incident to the use of carbolic acid in peritoneal surgery was referred to, and a plea for the substitution of chloral entered. The writer has seen carbolic acid used in peritoneal surgery and a solution of chloral used in the same class of cases, but has failed to appreciate any of the advantages claimed for the former. Chloral, he thinks, provokes and facilitates cicatrization and granulation, opposes the formation and degeneration of pus, and neutralizes or limits the morbific action of all septic poisons. The writer recognizes a field for Battey's operation, but thinks the full limits of its application have not been definitely settled. He has witnessed the effects of this operation by abdominal section in three cases, and while all of them recovered from the operation, the impression has been left that the operation is not free from the dangers common to abdominal surgery.

Nephrectomy, nephrotomy, and nephrolithotomy, and the conditions which call for these operations, are reviewed at length. One case of pyonephrosis successfully treated by nephrotomy is reported. The case occurred in a young man whose family history showed a marked tendency to nephritic troubles. His father was at the time insane from Bright's disease, and his mother was an imbecile from the same cause, while a brother and the patient himself had been operated upon for stone in the bladder. The pyonephrosis was treated by lumbar section, drainage-tubes, and antiseptic washes. The writer thinks, from a study of the literature upon the subject, that extirpation of the uterus for cancer is entitled to the earnest consideration of even the most conservative surgeon; but until there is unity of opinion concerning operative interference in cancer, there must be diversity of opinion concerning extirpation of the uterus for this malady. Extirpation of the uterus for uterine myoma, fibroma, fibro-cystic, and other uterine tumors, he thinks is clearly indicated where life is endangered or rendered unbearable. Porro's and Müller's modification of the Cæsarean operation are dwelt upon, and the operation and claims of gastro-elytrotomy, rupture of the uterus, and abdominal, intestinal, and tubal pregnancy also receive due notice in the report. As a last resort, operative interference in perforation and obstruction of the intestine is urged. The exploits of Billroth, Wölfler, and others in this field of operative surgery are fully brought out in the report. Operative interference for the removal of foreign bodies, for rupture of the bowels from falls, blows, wounds—and especially gunshot wounds—is, the writer thinks, strongly indicated whenever a fatal issue is apprehended. He concludes by insisting that in spite of the bright outlook for abdominal surgery, we cannot ignore the fact that the course over which the patient has to run after the surgeon has invaded the peritoneal cavity is beset with many dangers. The conditions conducing to a favorable or fatal issue are so evenly balanced that the most trivial factor may determine the result. No surgeon, he thinks, can have seen much of abdominal surgery without learning to appreciate the importance of little details—moments spent in controlling hemorrhage, in thoroughly cleansing the peritoneal cavity, and in looking to thorough drainage, are golden moments to the patient. The good resulting from such precautions far outweighs the danger incident to prolonging the operation.

MISCELLANEOUS BUSINESS.

After reference of the above essay and the awarding of the prize, on motion of Dr. Benj. Blackford, of Lynchburg, it was

"*Resolved*, That hereafter, the Committee on Nominations of Officers shall be empowered to submit the nomination of a Fellow for President, together with the other annually elective officers of the Society."

Evening Session.—On nomination, Dr. J. E. Chancellor, of Charlottesville, was elected to deliver the

ANNUAL ADDRESS TO THE PUBLIC AND PROFESSION

next year.

ALCOHOL—ITS USE AND EFFECTS AS A BEVERAGE AND MEDICINE,

was the subject for the Ex-presidents' Medical Prize. Dr. John F. Winn, of Richmond, read the first of the medical essays in competition. He gave the history of stimulants as phlogistics and antiphlogistics, passing rapidly from the earliest ages, up to Broussaism, and then to Todd's views. He remarked upon the rapid advance made by the profession since that day, both by clinical experience and physiological experiment, and quoted the resolution adopted by the American Medical Association, in 1878. He estimates the annual amount of spirituous liquors drunk in the United States, to be about 220,000,000 gallons. He next considered the use of alcoholics as beverages. As to the primary action of alcohol, it passes rapidly into the blood, altering the form of the red corpuscles, and causing them to adhere in rolls, and thus destroying their vitality; and by its affinity for water prevents or produces coagulation of the fibrine. Paralysis of the vaso-motor nerves is the next result leading to congestion, which is the first stage of acute alcoholism; the second stage being excitement and exhaustion of the spinal cord, with want of coördination of the muscular system; the third, a stage of unbalanced reasoning and volitional power; and lastly, a stage of complete collapse of nervous power.

With respect to the *food* value of alcohol, he stated at length the views of its advocates as well as of its opponents. It is conceded that the temperature is reduced and the elimination of carbonic acid is diminished, and the weight of authority seems to warrant the assertion that these results are due to the power that alcohol has in delaying metamorphosis of tissue, and that this delay in tissue change is caused by the

oxidation of alcohol into aldehyde and acetic acid at the expense of the oxygen which should be applied to the natural heating of the body. Dr. Winn classified its *secondary* effects into four degrees:

First, the *mechanical* effects, due to arterial relaxation, generally exhibited about the age of 25 or 30, in cardiac hypertrophy and arterial degeneration; in that well-known sclerosis and production of adventitious connective tissue in the various organs of the body.

Second degree is marked by those mental phenomena showing the deleterious influence of alcohol on the cerebral centres, generally indicated by loss of memory and speech.

Third degree marks that stage of insatiable craving for liquor (dipsomania), and those periodic forms of inebriety known as mania-a-potu.

Fourth degree. Here the most solemn fact of these mental and moral obliquities is shown in the progeny of the inebriate, in the form of idiocy, epilepsy, and insanity.

As to its use and effects as a medicine, the therapeutical application of alcohol is so narrowed that it can hardly be called more than a general stimulant. It is not a *direct* cardiac stimulant, but its effects are obtained indirectly through its paralysis of the "organic nervous chain" giving the heart's action increased frequency but "a weakened recoil stroke." Its physiological action does not warrant its employment in the treatment of hemorrhage, unless life is imminently threatened. As a simple antipyretic, it is very inefficient, and should be combined with other antipyretic agents. Its physiological action and clinical experience suggest its use when the heart's action is weak and rapid, the skin and tongue being at the same time dry and harsh. Delirium does not always contra-indicate its use. Congestion or inflammation of the liver or kidneys requires it to be given with great caution. As to dose, the effect produced is the best guide. As a rule, from four to eight ounces of brandy in the twenty-four hours will suffice. He would recommend the general rule laid down by Sir William Jenner and Prof. Loomis—never give stimulants indiscriminately; when in doubt as to giving or withholding stimulants, it is safer to withhold them; when given, watch carefully the effect of the first few doses.

Whether or not alcohol in diphtheria is an "antiseptic" or an "antidote" in the strict sense of these terms, as stated by M. Sauné and Dr. Chapman, there is a diversity of opinion; but clinical experience shows it to be absolutely essential.

In referring to its employment in phthisis, Drs. N. S. Davis and Austin Flint, Sr., are of opinion that alcohol exerts no prophylactic power. The former also believes that alcohol does not retard the development of the disease; while the latter has recorded the history of sixty-two cases of arrested tuberculosis. In nine cases, recovery was apparently complete.

In phthisis, if the effect of administration be that of a cordial, good may be expected from its use; if the effect be discomfort, alcohol will be a disadvantage.

In conclusion, Dr. Winn alluded to the injustice oftimes heaped upon the medical man for being accessory to the perverted habits of some of the unfortunates, and he would insist that physicians be more guarded in their advice as to the use of alcoholic liquors, and when in their good judgment they are indicated, prescribe them as definitely in time and dose as ether or chloroform, or any other agent.

DR. M. G. ELLZEY, of Washington, D. C., next read his essay on the same subject. As a beverage he discussed the effects of a moderate use of alcohol upon persons in health; first in creating a new physiological want, which is not a mere taste, but a systematic demand, peremptory, irresistible, and hereditary. Full statistics fortified this position. When the indulgence is carried to drunkenness, then we meet the deadliest evil of modern times. Dr. Ellzey then passed on to discuss the *Physiological Action of Alcohol*, mentioning well-known facts. He thought that pure old rye whiskey is less dangerous than other whiskeys, or French brandy. The adulterations of beer make it likewise dangerous. All stimulation is temporary and is followed by languor and depression. Referring to Dr. Hammond's experiments, Dr. Ellzey concluded that alcohol may temporarily and successfully supplement deficient food supply without bad consequences, but if the food supply is sufficient, then, even in small quantities will alcohol be followed by unpleasant effects. It should be used only in temporary emergencies or wasting disease. While it is established that some is eliminated undecomposed, the greater part is oxidized in the system. Dr. Ellzey then cited instances of the depressing and exhausting effects of whiskey upon laborers in harvest fields, upon soldiers, arctic explorers, etc.

The Use and Effects of Alcohol as a Medicine, were then pointed out; its advantage to the military surgeon in the field could not be over-estimated, in all cases of formidable surgical shock, in many severe and malignant diseases, in cases of venomous snakebites, etc., the advantage of alcohol in destroying micrococci and bacteria, etc., its value in supplying tissue in typhoid fever, consumption, etc. Especially in the last-named disease does Dr. Ellzey think *old rye* whiskey of great value, even more valuable than cod-liver oil, and the phosphorous compounds. The great need in this morbid condition, as in typhoid fever and other diseases, is *food*. Alcohol, properly used, is a food; and has this advantage, that *it enters the circulation without digestion*. Carbo-hydrates are nutritious only after some chemico-vital changes; all of which processes task the already insufficient supply of vital energy. "But alcohol takes a direct road to the circulation, taxing none of the vital organs, but rather giving a fillip to these energies, *en passant;* and once in the circulation, it enters forthwith upon its usefulness, suffering oxidation and liberating heat and other forms of energy, *pro re nata*." It ought always to be judiciously prescribed and used.

The anæsthetic effect of alcohol was remarked upon. As such it is useful in hysteria, and allied complaints. Especially in tetanus may we obtain great advantage from it. In some forms of dysmenorrhœa, whiskey is of great value.

In view of the hereditary tendency of inebriety, physicians should always be cautious as to whom they administer alcohol.

Dr. Ellzey conceives it to be foreign to the purpose of the essay to discuss the evils of drunkenness. Neither did he attempt to exhaust the therapeutical uses of alcohol.

The facts related by the author "constitute alcohol the greatest of physiological luxuries—a *magnum bonum Dei* in its skilful, scientific, and legitimate use; but in its *abuse*, a destructive and terrible agent, Satanic in its far-reaching, all-pervading power for mischief."

DR. FREDERICK HORNER, of Marshall, Va., as a contestant for the prize, read the third and last of the essays on the same subject. After defining alcohol—stating briefly its preparation, physical qualities, chemistry, history, etc.—he related some instances of its fatal toxicological effects. He spoke of the visceral and cerebral effects of the drug, and the pathological appearances which simulate those of inflammation and softening of the mucous membrane of the stomach, with cerebral congestion and sanguineous or serous extravasation in the brain and lungs. The blood is less coagulable, due to the destruction of fibrin. The improper continuous use of alcohol leads to insanity.

As a beverage, the appetite is generally acquired. As an illustration of the possible hereditary effect of habitual drunkenness, he instanced the case of a boy, 15 years old, arrested in New York for drunkenness. But he was not drunk, nor had he been drinking. He had never been able to walk without staggering. His speech was that of a person intoxicated, and, when excited, he would mutter and reel. But he was the son of an inebriate father. He referred to the annual amount of tax and revenue from alcoholic beverages for 1880, and stated that $700,000,000 were expended for such beverages in the United States annually. He pointed out the fearful amount of crime that seems to result from the traffic, and the great additional expense to corporations caused thereby.

As a medicine, alcohol, in small quantities, as a cardiac and brain stimulant has always been conceded to be useful in adynamic conditions, such as typhus and typhoid fevers, puerperal septicæmia, consumption, diphtheria, after sudden and large hemorrhages, functional gastrodynia, some forms of sea-sickness, some female nervous disorders, etc. For fevers, wine is preferable. Brandy or whiskey is better for blood-poisoning; and lager beer is useful when the nervous and visceral systems are implicated, etc.

In many instances alcohol exerts a pernicious influence on the heart. Alterations in the structure of the bloodvessels sometimes occur. Sometimes the heart's action is quickened, and the blood driven, therefore, more forcibly to the brain. Hence increased danger of cerebral hemorrhage.

Delirium is an example of the toxic effects of alcohol. The habitual use of alcoholics by young persons tends to diseases of the kidneys and liver. In confirmed inebriates, the organs are destroyed. Thus the origin of alcoholic phthisis, fatty degeneration and cirrhosis of the liver, cerebral, spinal, heart, and other diseases.

He closed by an appeal to the profession to be cautious how they administered the drug—"Striving to better, oft we mar what's good."

AWARD OF THE PRIZE.

The first ballot as to the superiority of one of these three essays over the others gave a majority vote to neither of the contestants. Many members who had not heard the full reading of the three essays declined to vote at all. The second ballot resulted as follows: Dr. Ellzey, 14; Dr. Winn, 13.

The prize was accordingly awarded to Dr. Ellzey.

SEPTEMBER 15TH, THIRD DAY—MORNING SESSION.

THE TREASURER'S REPORT

was presented, showing receipts of $720, and expenditures of $713.59, leaving a balance of $6.41 in the hands of the Treasurer, with the Society out of debt. At a later hour, the Auditing Committee reported that the accounts were correct.

ABNORMAL MENSTRUATION

was announced as the subject selected for general discussion. DR. SAMUEL K. JACKSON, of Norfolk, was called on to read a paper which he had prepared, and which bore on the subject named. In response, he reported

SOME CASES OF HYSTERO-EPILEPSY AND HYSTERO-CATALEPSY.

His paper consisted mostly in a detail of cases, with remarks suggested by them. The *first* case was that of a girl, in humble life, aged nineteen. The Doctor found her, five months after the attack began, lying on her back, her head slightly elevated, eyes fixed, complete paraplegia, and probably anæsthesia of the lower limbs, with perfect rigidity of these, and partially of the upper. When she attempted to move her arms, violent and rapid vibrations would occur, the arms being at right angles to the body. She made her wants known only by "grunts." She could not flex her fingers. Some four or five years previously, she was in the habit of jumping off a high porch. One day, she and a companion spent the whole day in this amusement. That afternoon, she had a "fit," which lasted some hours. The fits recurred frequently—especially during her menstrual periods. This state culminated in cataleptic attacks. Dr. Jackson made a vaginal examination. There was retroflexio uteri. Not being prepared to enter at the time upon proper treatment, the Doctor simply elevated the retroverted fundus. Partial relief resulted. At his next visit, the patient was sitting up. She slowly recovered, until she was able to walk on the street.

Case II.—Woman, aged 22, shirt-maker, stout, active, and strong; used *heavy* sewing machine. She had had menstrual "irregularities" often. On one menstrual occasion, a cataleptic attack occurred, which remained four weeks, until her subsequent menstruation. Then she was well for four weeks. She now failed to menstruate, and the same cataleptic condition recurred. Later, the flow became regular, and she is perfectly well. In pointing out the peculiarities of this case, Dr. Jackson called special attention to the fact that, when she was not disturbed, she remained perfectly motionless; there was, also, complete hemianæsthesia of the right side, with exalted sensibility of the left side.

Case III.—April, 1879. Girl, aged 18 years. She was easily excited, and slept but little. Menstruation was deficient, with "irregularity." Much mental perturbation, on account of association with an insane girl, after the patient went to school-teaching. She developed clonic spasms, commencing with a tremulous agitation of the arms—increasing to jerking. Dread of apprehending the lunatic or idiot, above referred to, would greatly frighten her. Such an attack would sometimes end suddenly, and at others she would remain in a cataleptic condition. A curious hoarse barking cough almost always followed these attacks. This cough gradually became relieved.

Case IV.—Miss —, age 15, suffering pains and "nervous tremblings" in both arms, with a sensation as if being "unhooked." Her mother thought she overstudied, but such does not seem to have been the fact. She fell into a profound sleep and so remained for four weeks—the only apparent act of consciousness being that of swallowing after much shaking and slapping. Then imperfect menstruation commenced, during which she opened her eyes; but this was followed by another four weeks of catalepsy, with her eyes wide open. After the subsequent monthly period, there was occasional opening of her eyes, but nothing could arouse her. This condition lasted five months. There was almost total anæsthesia of the whole body with loss of will-power. After the fifth month, she recovered, and became more sprightly than before her attack. The cause of the trouble was very obscure—the deficient menstruation being the only abnormal condition observed. The uterus was normal in size and position; but there was a bend of the sacrum about midway in its length, nearly at right angles, due to a fall in early life. Probably the sacral nerves were pressed upon by the engorged uterus during her monthly period, but no examination proved this to be a fact.

Case V.—Miss —, age 15, sprightly; in April, 1882, had a chill, and another May 4th. She began to jerk and jump. A neighboring doctor pronounced the attacks hysterical. The spells at first lasted from 10 to 20 minutes, but the duration soon increased to from 2 to 4 hours, and they were so violent as to require three or

four men to hold her to prevent personal injury. She would sometimes throw her head back between her shoulders, with her face flat on the bed, and throw her feet back above the head. It was impossible to straighten her. These attacks recurred until the last of June. She began then to go off suddenly into unconscious states, when all at once she would commence laughing and talking to imaginary persons. Sometimes nothing could arouse her—not even the firing of cannon nor deafening peals of thunder. At other times, she could hear the faintest whisper. About June 1st, she came under Dr. Jackson's observation. There had been complete amenorrhœa for two months. Agents used for the relief of this condition mitigated the paroxysms and an entirely favorable change in her condition resulted until August 20th. Since then, there have been strange periods of double consciousness, with cataleptic attacks of from half an hour to two or three hours in duration. In these attacks she would talk as though in company with distant friends and would tell where they were and what they were doing; and, strange to say, letters received by the family from the parties verified her accounts. A number of instances were related where her statements as to distant persons and things proved entirely correct. There is great hyperæsthesia of the optic nerve. She is still under treatment and is improving.

DR. J. E. CHANCELLOR, of Charlottesville, followed with a paper on

ABNORMAL MENSTRUATION.

After defining menorrhagia and metrorrhagia, he said he had met with these forms of abnormal menstruation more frequently than any other. General plethora, certain climates and habits of life, chronic metritis, chronic degeneration, fibrous tumors, polypi, fungous affections of the womb, retained products of conception, subinvolution, displacements of the uterus, were among the more prominent causes named. As regards displacements, Dr. Chancellor thinks "when retroflexion gives rise to a diminished menstrual flow, we have the attending chronic inflammation, with hypertrophy; and when retroflexion is attended by menorrhagia or increased flow, we have subinvolution of the organ." He laid special stress upon subinvolution as a cause of menstrual abnormalities.

Treatment consists in quiet, cool apartments, hard bed, iced acidulated drinks, cloths wrung out of cold water applied over the vulva, anus, and thighs, elevating foot of bed, judicious use of hæmostatics—such as ergot, gallic acid, cannabis Indica, etc. In more serious cases, tampon the vagina with a bag of powdered alum, or apply tannic acid to the os; or, after dilatation of the os with tents, hot water may be applied with a sponge; or then tincture of iodine may be used, or even, if necessary, one part of solution of persulphate of iron, diluted with two parts of water. Of course here and there the curette may be demanded. He closed his paper with the report of a case of metrorrhagia, in which the curette saved the life of the wife of a member of the Society.

A general discussion followed, but it took such wide latitude that it would be impossible to do justice to the speakers, without reporting in full their remarks.

Diphtheria was selected as the subject for discussion at the next annual session, and the Society, after adopting the usual resolutions of thanks, adjourned.

RHODE ISLAND MEDICAL SOCIETY.

Quarterly Meeting, held at Providence, Sept. 21, 1882.

(Specially reported for THE MEDICAL NEWS.)

THE Society assembled at 10 A.M. in Lyceum Hall, Providence, the President, DR. JOB KENYON, in the chair.

DR. GEORGE D. HERSEY, *Secretary*, read the records of the annual meeting, which were approved.

REPORTS FROM DELEGATES TO OTHER SOCIETIES.

DR. J. H. ELDRIDGE, of Greenwich, delegate to the American Medical Association, made a verbal report. The cordial and unlimited hospitality extended to the delegates was alluded to in terms of highest praise, as were also the men representing the profession throughout the West and Northwest.

DR. W. E. ANTHONY, of Providence, delegate to the New Hampshire Medical Society, made a verbal report, and DR. W. O. BROWN, of Providence, delegate to the Massachusetts Medical Society, presented a written report.

THE CENSOR'S REPORT

was next read by DR. S. S. KEENE, Secretary of the Board.

The following named gentlemen were recommended for fellowship and duly elected: Drs. George F. Bliven, Charles E. Woodbury, and Frederic T. Rogers.

DR. J. H. ELDRIDGE then read a paper on

TEDIOUS LABOR FROM RIGID OS.

The great frequency of protracted labors from this cause was alluded to—occurring chiefly in short and stout women in high health and primiparæ. It was not the writer's intention to consider those cases due to malformation of the maternal pelvis—to fœtal deformity, to spasm of the lower segment of the uterus, or to a previous occlusion of the os. The physiology, duration, and object of the first stage of labor were spoken of. This stage prolonged, painful, and the most distressing, often in *normal* cases, in *abnormal* ones, amounts to the fiercest internecine strife between the nervous organism of the patient and her powers of endurance. The traditional treatment of these cases of forty or fifty years ago, was mentioned, viz: The dose of castor oil, the emollient enema, venesection, tartar emetic, ipecac, belladonna ointment to the cervix, and most important of all "patience," or giving nature time to do her perfect work. In more recent years the use of ether, chloroform, chloral hydrate, opium, dilators, the colpeurynter, etc., has greatly modified the conduct of such labors.

The writer had found the use of chloral of the greatest service—in dose of gr. xv per orem, or gr. xx per rectum, and repeated every two hours if required, to blunt the sensibilities and cause drowsiness. When the os, between pains, is an inch or an inch and a half in diameter, and yielding little or none, it may be advisable to hasten dilatation by gently introducing the fingers during the pains, or to press back the anterior lip of the os over the fœtal head. In many cases it is necessary to decide whether to hasten the labor on to delivery, or to give the nearly exhausted patient a period of rest, to accomplish which a subcutaneous dose of morphia may be employed. A full dose of quinia (grs. xv) may sometimes be given for its decidedly stimulating effect on the uterus, when such effect is desirable.

The writer then briefly gave a few cases from his own practice.

Case I.—Occurred in 1855. Woman 38 years old—her third confinement. She had been in labor 24 hours, was much fatigued and very irritable. On examination the os was found to be high up, but little dilated, and very rigid. The patient was at once raised up in bed and "bled" freely from the arm. At the end of half an hour the os was much less rigid, and a natural delivery occurred within an hour.

Case II.—Was that of a woman 40 years old, stout, in fine health, and in her third confinement. The membranes ruptured early, the os was rigid and high up, and progress very slow. Ether was asked for by the

patient and administered for eight or ten hours. When not under its influence the woman was wild and unmanageable. A safe delivery resulted, but the case was trying to the operator and to the family.

Case III.—Was that of a primipara, on the third day of labor the os uteri was sensitive and rigid. Chloral hydrate, ℈j in aq. ℥ij, was given per rectum, and repeated twice at intervals of two hours. The effect was prompt and satisfactory.

The writer, in closing, deprecated the growing tendency to interfere and hasten normal labors, and said the lying-in-woman, during the tedious first stage of labor, should be patiently and tenderly managed.

On motion, Dr. Eldridge's paper was referred to the Committee on Publication.

DR. ANTHONY then read a paper written by DR. GEORGE CAPRON, entitled

MISCARRIAGES AND SOME INCIDENTAL REMARKS ON CLOSELY ALLIED SUBJECTS.

The writer had come to the conclusion that the prevalent conduct of miscarriages was not the safest or most advantageous, though he made no pretension to having kept the run of all that had been published on the subject, even in New England, and the opinions now advanced were formed regardless of authority, and based wholly on personal experience in a practice covering sixty years.

When called to attend a case of uterine hemorrhage, where an impending miscarriage is suspected, there is urgent necessity of making a certain diagnosis. The length and position of the cervix, the mammæ and areola, the color of the mucous membrane of the vulva and vagina, which in the pregnant state changes from the bright-red or vermilion tint to a dingy purple, and morning sickness, were said by the writer to be the most reliable diagnostic points, though no one of them alone was sufficient.

In regard to the prognosis, in case of threatened miscarriage, if the patient has had a chill followed by headache, if pains are occurring regularly, if there is hemorrhage accompanied by coagula, and if the os is so patulous as to allow the examiner's finger to touch the ovum, there can be little hope of prevention.

In the treatment of these cases there is no specific medicine that will be efficient in case the membranes have ruptured, or a portion of the placenta become detached. The virburnum primifolium may be used, along with perfect rest in bed, cooling acid drinks, light diet, opium, and the application of *cold* to check hemorrhage. If it is possible to remove the ovum, do so, when the contraction of the empty uterus will check the hemorrhage. But in cases where the os is but little dilated, and the ovum cannot be extracted, and the hemorrhage is so free that it is not safe to wait for the action of cold or opium, it is advisable to use the tampon. The writer prefers wads of cotton, wet in solution of alum, for the tampon, and if the use of the speculum is not practicable, by inserting two or three fingers of the left hand back of the perineum, the operator can readily introduce the cotton plugs. If clumsily done, however, tamponing is painful to the woman, and in post-partum hemorrhage at term, it is unsafe.

Having had no personal experience in the use of *hot* water as a hæmostatic, the writer only asserts the excellence of *cold* water or ice applied in the vagina or even within the uterus itself.

Many miscarriages are attended by very severe pain; these require the use of morphia, and if antimony is combined with it, the danger of inflammation is diminished. Ergot should not be given until the os is sufficiently dilated to admit the expulsion of the ovum, which otherwise might be shut in by the contracted uterus. Ergot is very reliable and sure to produce its effects, and hence must be given with great care and caution. The writer had used matico at times with good success.

A most important question is in regard to the placenta in case a small fœtus is expelled, leaving the after-birth partly or wholly within the uterine cavity.

If the placenta can be removed easily, it is best to do so, but it is not safe to forcibly extract it by any method, and thereby admit air into the womb. The danger is much less from allowing it to remain. Even if the placenta protrudes through the os, it may not be safe to remove it. If there be considerable resistance to its removal, leave it to nature.

In labor at term the placenta should always be removed if its expulsion does not occur naturally, and a very important question is the period of gestation at which the placenta may, with safety, be left to return. After *six* months it is safer to remove it.

The condition called septicæmia, the writer thought a most mysterious one, and one that was not recognized or heard of fifty or sixty years ago. In a series of twenty-five hundred lying-in cases that had come under his own personal knowledge and observation, there had occurred only one case of septicæmia.

On motion, Dr. Capron's paper was referred to the Committee on Publication.

DR. E. P. STIMPSON gave some interesting

STATISTICS OF VACCINATION.

He had used bovine virus only, and had vaccinated 523 times in 481 individuals; the operation was successful in 207 primary and 220 secondary cases. One individual had previously been vaccinated thirty times with no effect. The thirty-first time was completely successful.

Reports of cases were next called for.

DR. E. T. CASWELL reported

FIVE CASES OF LITHOLAPAXY

performed by him since last March, making ten in all that he has reported.

In this last series of five—

Case I.—Was that of a man aged 60 years, stout and fat. The stone—of uric acid—weighed 173 grains. Time of operation, a little more than an hour. Good recovery.

Case II.—Age 69, the stone was uric acid, and 47 grains in weight, but had caused very severe symptoms.

Case III.—Man 47 years old. At a previous examination a sound, passed seven and a half or eight inches, struck a stone, which gave a positive metallic clink, but did not seem to be in the bladder. At the time of the operation the sound apparently dislodged the stone, which on crushing proved to be soft. It weighed but 15 grains dry, and on examination proved to be necrosed *bone* with a thin incrustation of phosphatic salts.

Seven weeks after the operation, Dr. Caswell was called to see the man again, and found a perineal swelling simulating an abscess, but on opening it no pus was found. This swelling entirely subsided, and in two weeks time there was to be found a suspicion of bone at the bottom of the opening, which had no connection with the urethra. The patient had had no history of syphilis, or of injury, or of abscess; nor had he ever introduced anything into the urethra. The origin of the necrosed bone was therefore entirely uncertain.

Case IV.—Patient was a woman aged 51. The stone weighed when dry 100 grains. (This case was reported in THE MEDICAL NEWS for August 26, 1882.)

Case V.—The patient was a stout middle-aged man aged 59. Stone weighed 1040 grains *wet*, and 815 grains *dry*. Two hours were occupied in the operation. There were two calculi—uric acid—one having an oxa-

late of lime nucleus. The patient recovered well, and was out in ten days from the time of the operation.

DR. CASWELL further remarked that he had entire confidence in the operation which was not objectionable in patients of any age, and was much less dangerous than lithotomy. One thing is certain—the element of time in operating need not be taken into account, and the operator should not attempt to do quick work, gentleness in manipulation being all-important.

DR. D. E. CONE, of Portsmouth, reported a case where a phosphatic calculus formed on the end of a silver catheter that was allowed to remain in a patient's bladder for four weeks. The calibre of the catheter was also incrusted with the same deposit.

DR. BATCHELDER, of Cranston, mentioned a similar case.

DR. W. J. BURGE, of Pawtuxet, reported a case of *Puerperal Eclampsia*.

The Society then adjourned.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, September 7, 1882

J. SOLIS COHEN, M.D., VICE-PRESIDENT, IN THE CHAIR.

Case of Carcinoma Mammæ (presented by DR. C. B. NANCREDE, for Dr. Charles Wirgman).—Mrs. Josephine M., aged 48 years, married at 23, the mother of three children, the last born sixteen years ago. Had nursed all her children, but the last died from marasmus, owing to the small amount of milk the mother had, although lactation was free after the first two confinements. She never had had any abscess of breast, traumatism, or eczema of the nipples, although she had always experienced pain and uneasiness in the right breast when nursing. There was no trace of carcinoma in family history. A sister had had an enchondroma of one of the metacarpal bones. When young, the patient had suffered from dyspepsia, and on one occasion had had an attack of hæmoptysis. Of late years, Mrs. M. has grown very stout, although never robust nor strong. About the middle of June, 1882, she first noticed a lump in her right breast, at its upper inner quadrant, about the size of a hen's egg. A few nights previously she had been awakened by a severe lancinating pain in the right breast, but, experiencing no further inconvenience, she paid no attention to it. The mass did not seem to grow till after an exploring needle had been inserted, when the growth became softer, much larger, painful, and the skin and superjacent veins rapidly showed marked changes. I saw her Aug. 6, 1882, with Drs. Wirgman and Hearn, when the only additional points to be noted were that the growth was freely movable with the breast upon the chest walls, and that a mass the size of a pigeon's egg could be felt in the axilla, under the outer margin of the pectoralis major muscle. Dr. Wirgman removed the whole breast by two semicircular incisions, opened up the axilla, and removed all the glands up to the clavicle. This operation again emphasizes what Dr. S. W. Gross has specially insisted upon, viz., that although the axillary glands may appear before operation uninvolved, that when the axilla is opened, numbers are often found enlarged. This accords with my own repeated experience. Although slow in healing, the case has done well since operation.

This case presents special points of interest, to which I desire to call attention. In the first place, its history and appearance were eminently suggestive of a rapidly forming sarcoma, which was either cystic or what at once suggested itself to me before etherization, one into whose substance hemorrhage had occurred. Upon careful examination under ether, the discovery of the enlarged gland at once suggested the strong improbability of sarcoma, which view I abandoned. After the removal the macroscopic appearances once more threw doubt on the diagnosis, as there was for at least one-half, if not more, of the circumference of the growth, a distinct *appearance of a capsule*, and, as I had surmised, the tumor had been broken down by a hemorrhage into its substance. Subjected to microscopic examination, the specimen was again puzzling, since sections of the first piece embedded showed in every portion of their extent, with a few very slight exceptions, small spindle-cells of a connective-tissue type. Dissatisfied, I embedded a second piece, sections of which revealed a typical carcinoma of the soft variety. This again illustrates what I have many times insisted upon in this Society, viz., that either very large sections of growths should be made, as Dr. Seiler advocates, or sections from several and varied portions of the morbid mass should always be carefully examined.

Recurring Carcinoma of Mamma and Axillary Glands (presented by DR. C. B. NANCREDE).—The patient, Mrs. F., æt. 37 years, from whom the specimens were removed before the discovery of the primary tumor, about eighteen months back, was in perfect health, although from pecuniary losses she had undergone much mental anxiety since the Chicago fire. Hearing a vivid account, from a friend, of another case of carcinoma mammæ, her mind became deeply impressed, and shortly after she discovered a growth in the upper inner quadrant of the left breast, which continued to grow until it had attained at the time of the first operation to the bulk of a small orange, viz., one year after her first discovering it; she lost much flesh, from the time of the discovery of the growth; she had never suffered from any form of traumatism; had had no eczema of the nipple, and although she had borne one child a number of years back, and had suckled it, had never had sore nipples. There was nothing which could be fairly construed as an hereditary history of carcinoma. The primary operation had consisted in a removal of part of the breast. In less than two months after this a small nodule appeared in the cicatrix, while the axillary gland began to enlarge rapidly. On July 8, 1882, I saw her in consultation with Drs. R. R. Taylor and Harlow, when I found that there was a small nodule in the middle of the original cicatrix, while the axilla was occupied by the mass of indurated glands, which I here present. The growth partially embraced the axillary artery, since when the former was compressed the radial pulse was decidedly affected. Not being allowed to remove the whole breast, I freely excised the small recurrent growth, and after a tedious dissection removed the axillary tumor, laying bare the artery and vein for a space of over an inch, clearing everything out to the clavicle, and distinctly recognizing the coracoid process of the scapula. Although not the place for a clinical discussion, I cannot refrain from emphasizing the importance of the thoroughness with which this axillary dissection should be performed. Not a single gland should be left, enlarged or not. Properly conducted, there is hardly any hemorrhage, a vessel rarely requiring ligature. This case was treated on Listerian principles, but with a spray of acetate of aluminum, and the wound was dressed with the same. There was no inflammation, heat, pain, nor subsequent induration, and, if I remember rightly, the case required but five dressings, until the wound became superficial, and fewer would have been necessary had perfect coaptation been secured. One or two points where stitches made marked tension showed a surrounding skin blush, which disappeared on the removal of the stitch; immediately contiguous to this the wound-edge looked as

if made but a few minutes before, thus showing that the irritation of *tension* was the trouble, which, as before said, very rapidly disappeared when the deeply imbedded stitch was cut. The temperature rose to 100 2° at the end of the first twenty-four hours, after which it remained under 100°. The pain after the removal of the pressure of the button-stitches amounted practically to nothing, according to the patient's own statements, and it will be remembered that she had the experience of a former operation for comparison. I believe that this is the first case where acetate of aluminum has been used in this city in a Listerian operation, and its success disposes of the absurd statement that carbolic acid *is* Listerian.

Carcinoma of Stomach (presented by Dr. J. H. Musser).—The clinical aspects of this case were so definite that when this man applied to the Medical Dispensary of the Hospital of the University of Pennsylvania, for treatment, early in April of this year, it was without difficulty that malignant disease was diagnosed. He was a farmer of good habits, 53 years old, and previously in good health. For the last six months he had suffered from "weakness of the stomach," and general debility, which prevented him from working. He had lost much flesh, and had constantly a severe sickening pain in the epigastrium extending to the upper part of the lumbar region, which became much worse within an hour after eating. Appetite was poor, tongue clean and pale, bowels constipated, with troublesome flatulence. A tender, non-pulsatile, movable tumor extended across the epigastrium from the margins of ribs on the one side to a similar site on the other, one inch and a half above the umbilicus. He presented an anæmic, cachectic appearance.

Dr. H. Plank, of Morgantown, took charge of the case, and wrote me April 21, 1882, that he was much benefited by the treatment instituted, but was confined to bed by sheer exhaustion. June 5, the Doctor reported increased weakness and emaciation, and that the pain had extended along the left side to the same shoulder. He took but little nourishment and he commenced vomiting, June 10, undigested food, mucus and grumous purulent matter. He died June 20, of exhaustion, after a nine months' illness.

Dr. Plank kindly sent me the specimen I here present. One fourth of the pyloric end of the stomach is involved in the growth, which extends along the greater curvature for four inches, along the lesser two inches, and completely encircles the organ. The stomach walls in front of the diseased mass were dilated, the muscular coat being hypertrophied, and the mucus membrane congested. The mass encroached upon the calibre of the viscus so as almost to occlude it. The tumor consisted of three nodules, one of which was ulcerated on its mucus surface, and presented the appearance of a scirrhus. The glands in the lesser omentum were diseased.

Spindle-celled Sarcoma of Thigh (presented by Dr. J. Henry C. Simes).—The patient, from whom this specimen was removed, presented himself for admission to the Episcopal Hospital, on August 30, 1882. He is 60 years old, an Irishman, and gave the following history. Two years ago he first noticed at the lower and outer part of the thigh, a small swelling, which grew rapidly to the size of a hen's egg, when it was removed. Shortly after the wound had healed, a second tumor was noticed in the cicatrix, having the same characters as the previously removed growth. This was also removed by operation, and again, in a still shorter interval, a third similar growth was developed in the same locality, which was also removed by the knife. When admitted to my wards, there was found, upon examination, at the lower and outer part of the thigh, a linear cicatrix about two inches long, beneath and adherent to which, as well as to the surrounding integument, was seen a tumor as large as a walnut, movable upon the deeper tissues, painless, dense, and irregularly nodular. There was no glandular enlargement observable. No other tumors were present. The tumor was readily removed, being adherent only to the overlying skin, which was included in the incisions. Microscopic examinations showed that the neoplasm consisted entirely of large spindle-shaped cells, which contained large oval nuclei.

NEWS ITEMS.

The Progress of the Yellow Fever.—The convalescence of Brownsville, Texas, may be considered as having been established during the past week. It has suffered and has recovered. Hitherto, quarantine has been directed to preventing egress from the infected district; it may now well assume as part of its duty, the prevention of the ingress of fresh material, until the season of propagation has ended. The guard of one hundred and thirty men, established by the Marine Hospital Service between Laredo and Corpus Christi, has been withdrawn, as there are now no points of infection in Star and Hidalgo Counties, except in the vicinity of the river. The *Cordon Sanitaire* is now extended along the river from Laredo to the Arroyo Colorado.

At Pensacola, Fla., the disease continues unabated. The daily telegrams of the health board show that many of the cases are among the colored population. Hospitals have been established during the week for facilitating the nursing of indigent patients. To date (Sept. 25) there have been reported 517 cases and 54 deaths, as follows:

Up to and including Sept. 18, 217 cases, 29 deaths.

Dates.	Cases.	Deaths.
September 19th,	26	4
" 20th,	41	6
" 21st,	60	2
" 22d,	43	2
" 23d,	36	5
" 24th,	39	4
" 25th,	55	2
Total,	517	54

These have occurred in the city. No reports have been published concerning cases which may have developed among the shipping, although we know from the appearance in Hampton Roads of an infected vessel from Pensacola that there have been such cases.

The navy yard continues free from fever by virtue of a vigilant non-intercourse quarantine against the infected locality. There is much destitution among the 1700 residents in the guarded reservation. Except the paid pickets and a few laborers in the yard, no one has employment. Food is exceedingly scarce, as they are cut off from the outside world. The health authorities of Mobile have been requested to despatch a steamer with provisions for their relief.

On account of the continued freedom of New Orleans from fever, the precautionary guard instituted by Mississippi and other States on the river over their traffic with that city, will be discontinued on September 30th. The Louisiana Board of Health has not accepted this surveillance over the condition of New Orleans with the cheerfulness and good-will which it promised at the outset. It will be correspondingly relieved at the termination of the inspection system.

The following is a summary of the progress of yellow fever at *Brownsville, Texas*, for the *week ending September 23*, furnished by the Surgeon-General of the Marine-Hospital Service, compiled from official returns:

Dates.	Cases.	Deaths.
September 17th,	27	1
" 18th,	19	4
" 19th,	14	1
" 20th,	18	1
" 21st,	8	1
" 22d,	4	1
" 23d,	9	0
Total,	99	9
Previously reported,	1,771	94
Total during epidemic	1,870	103

In addition to above, there were two cases—no deaths—for Sunday, the 24th inst., which will be included in next week's summary. Five new cases and one death on Monday.

Reports indicate that the disease has been confined within the Arroyo Cordon on the Texas side, but that it has extended to many of the river towns and ranches on the Mexican border of the Rio Grande as high up as Guerrero. The Corpus Christi and Laredo Cordon has been removed and guards placed along the river, making a new cordon extending from the Arroyo to Laredo, thus cutting off all communication with the infected districts in Mexico.

At Point Isabel (inside the Arroyo Cordon) official reports give the following.

Dates.	Cases.	Deaths.
August 29th,	10	0
" 31st,	8	1
September 16th,	8	1
" 22d,	4	1
Total,	30	3

Official reports from *Pensacola, Fla.*, by mail, have been received by the Surgeon-General, to include the 21st of September, as follows:

Dates.	Cases.	Deaths.
September 16th,	19	1
" 17th,	8	0
" 18th,	27	1
" 19th,	26	4
" 20th,	41	6
" 21st,	60	2
Total,	181	14
Previously reported,	163	27
Total during epidemic,	344	41

CHOLERA IN JAPAN.—During the ten days from August 21st to 31st, there are reported as having occurred in Yokohama and vicinity, 465 new cases of cholera, and 281 deaths. Total since commencement of the epidemic, 3266 cases and 2000 deaths. On the 30th of August, an American, named Blass, was seized with the disease and died in less than twelve hours. He is the first adult foreign resident in Yokohama who has been attacked.

CHOLERA IN THE PHILIPPINE ISLANDS.—The cholera epidemic in the Philippine Islands, is still making fearful ravages, although the mortality is much less than it was a few weeks ago. At the beginning of this month the deaths in Manilla alone averaged 300 daily, and during the last two weeks of August, there were 4,550 deaths from the disease in the single province of Yloilo. The deaths at present number about 50 daily in Manilla, but reach the terrible total of nearly 200 in the surrounding country.

SMALLPOX IN ILLINOIS.—The Secretary of the State Board of Health, under date of September 20th, reports that smallpox is now practically at an end in Illinois. The efforts to obtain complete immunity by vaccination, however, should not be relaxed, for whenever there exists any considerable number of unprotected persons there is danger, as is shown by the history of the recent local outbreaks. That in Monroe County was caused by an infected mattress thrown into the Mississippi River, and which lodged on Staten Island, near Harrisonville. Some unvaccinated persons came in contact with the mattress, and a number of cases ensued. Thence it was carried into Randolph County, where it found a number of other unvaccinated individuals near Prairie du Rocher, and caused an outbreak among them, with three deaths at date of last report, September 14th. In Alexander County, near Goose Island and Promised Land, some nineteen cases and four deaths have resulted from infection brought also from the river. All these cases were among unvaccinated persons.

From present indications, the chief source of danger is along the Mississippi River, south of St. Louis. The Immigrant Inspection Service of the National Board of Health has diminished the danger of importations from the east to the minimum. Many of the Mississippi and Arkansas River counties have, however, been severely visited, and the conditions of life among the negro population of that region are not such as to warrant the belief that the contagion will be readily "stamped" out among them. It is liable to be introduced into the State from this source at any time until the disease dies out there for the want of material. And whenever introduced, it will find its victims among the unprotected.

HARVARD UNIVERSITY VETERINARY SCHOOL.—A veterinary department is to be opened at Harvard this fall. The course is arranged to cover three years of theoretical and practical instruction.

UNIVERSITY OF LOUISVILLE.—The Faculty of the Medical Department of the University of Louisville has undergone some very important alterations. Prof. T. S. Bell is transferred from the chair of the Science and Practice of Medicine, to the newly created chair of State Medicine and Sanitary Science.

Prof. L. P. Yandell, so long the popular teacher of Materia Medica and Therapeutics, and more recently the occupant of the chair of Diseases of Children and Dermatology, will hereafter teach the Principles and Practice of Medicine and Clinical Medicine.

Prof. Parvin, formerly of Indianapolis, the well-known editor of the *American Practitioner*, has accepted the chair of Obstetrics, made vacant by the death of Prof. Crowe.

Prof. Holland has been transferred to the chair of Pathology, Clinical Medicine, and Diseases of the Nervous System, and Dr. Roberts has been promoted to the chair made vacant by the death of Prof. Cowling.—*Nashville Journ. of Med. and Surg.*, Sept. 1882.

STATE ANALYSTS.—Prof. E. S. Wood, M.D., of Harvard College, and Prof. B. F. Davenport, M.D., of the Massachusetts College of Pharmacy, have been appointed the analysts under the Act relating to the adulteration of food and drugs in Massachusetts.

JAPANESE MEDICAL LITERATURE.—Two hundred and sixty-seven medical works were published in Japan in the Japanese language in 1881.

POISONOUS BULLETS.—A German journal refers to a discovery by M. Gros, of Paris, with regard to the complaints which were made of the use of poisoned bullets by the combatants on both sides during the Franco-

German war. He explains that the construction of the modern breech-loading arms causes the bullet to convey with it a portion of the hydrocyanic acid which the explosion of the powder has caused to be accumulated in the barrel. Even if poisoning to a mortal extent does not take place, it is remarked that the healing of wounds is materially retarded by this circumstance.—*Medical Times and Gazette*, August 26, 1882.

AN HONORABLE CITIZEN.—The *Monthly Sanitary Bulletin*, of Lowell, Mass., for August, gives an account of the abatement of a soap-boiling nuisance which was established fifty years ago when there were few houses in the locality, but which is now surrounded by a dense population. In consequence of complaints coming to the Board of Health, its members called on the owner, rehearsed the complaints, and stated what was the law and its decisions on the subject, whereupon a prompt acquiescence was given to the requirement of the Board to have the grease rendering establishment removed to a less thickly settled locality. "This decision," says the *Bulletin*, "while it will highly gratify the residents in the vicinity, reflects honor upon the owner, as he must make quite a sacrifice in the change."

KOUMISS.—Koumiss, made at home, costs about fifteen cents a quart. The *Ledger*, of this city, gives the following recipe for its manufacture: "Fill a quart champagne bottle up to the neck with pure milk; add two tablespoonsfuls of white sugar, after dissolving the same in a little water over a hot fire; add also a quarter of a two-cent cake of compressed yeast. Then tie the cork on the bottle securely, and shake the mixture well; place it in a room of the temperature of 50° to 95° Fahr. for six hours, and finally in the ice-box over night. Drink in such quantities as the stomach may require. It will be well to observe several important injunctions in preparing the koumiss, and they are: 1. To be sure that the milk is pure; 2. That the bottle is sound; 3. That the yeast is fresh; 4. To open the mixture in the morning with great care, on account of its effervescent properties; 5. Not to drink it at all if there is any curdle or thickening part resembling cheese, as this indicates that the fermentation has been prolonged beyond the proper time." Make it as you need to use it. The virtue of koumiss is that it refreshes and stimulates, with no after-reaction from its effects.

INJECTION OF SALT SOLUTION AFTER HEMORRHAGE.—DR. E. SCHWARZ reports, in the *Berliner klin. Woch.*, August 28th, a case of collapse from hemorrhage in which he injected 1000 cc. of 0.6 per cent. salt solution. The patient regained consciousness, but died in six days.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending September 16, 1882, indicate that remittent fever has considerably increased, and that diarrhœa, bronchitis, cholera infantum, cholera morbus, neuralgia, and whooping-cough have increased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending September 16, and since, at 20 places, scarlet fever at 8 places, measles at 2 places, and smallpox at 2 places, as follows: in Berlin Township, Ionia County (convalescent), September 12: at Ionia, September 18.

PUBLIC HEALTH IN CONNECTICUT.—The Secretary of the State Board of Health, in his monthly report, states that the mortality for July was exceptionally large, especially in the cities, and that cholera infantum stands first among the causes. Typhoid fever is reported to be steadily regaining its old prominence, while not entirely displacing malarial disease. Smallpox apparently is at last stamped out. There has been very little scarlet fever reported, and the mortality is slight. Whooping-cough still prevails. An epidemic of measles was reported from Nangatuck, and it reappears in the mortality tables in several cities. Stamford, South Manchester, Oxford, and Wilton, report quite a prevalence. Diphtheria is reported at Montville, Mystic, Norwich, Avon, Suffield, and Plainfield, Malarial diseases are prevalent, the type ranging with the duration of the disease.

THE SIBERIAN PLAGUE.—A telegram to the *British Medical Journal*, reports that the Siberian plague is manifesting itself in an unusually widespread and alarming manner. Reports of its appearance have been received from the most widely separated quarters of European Russia, and a case of death from the pestilence is announced from Odessa.

OBITUARY RECORD.—DR. GEORGE CAPRON, the oldest physician of Providence, R. I., died of apoplexy, Sept. 21st, at the age of 80 years.

Dr. Capron had been in constant and active practice for more than sixty years, and worked up to the moment of the outset of his brief and painless illness, which occurred the 17th inst. Soon after he was attacked, he spoke of a paper he had just completed, to be read at the approaching meeting of the Rhode Island Medical Society, of which he was President in 1850, and always an active member. He desired a friend to convey his regards to the Fellows, and tell them he should never meet with them again.

—— M. L. A. DESMARRES, for a long time one of the most eminent oculists of Paris, died suddenly, on August 22, at Neuilly. He was born on September 22, 1810, at Evreux.

NOTES AND QUERIES.

NITRATE OF URANIUM IN INCONTINENCE OF URINE.

To the Editor of THE MEDICAL NEWS.

Dear Sir: Having lately heard of the successful treatment of an obstinate case of incontinence of urine in a child by an irregular practitioner with nitrate of uranium, would you allow me to ask through your columns if any of the profession know of its use, or have had any experience with the drug named?

Yours, very truly,
ALEXIS D. SMITH.

PHILADELPHIA, September 21, 1882.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 18 TO SEPTEMBER 25, 1882.

SPENCER, WM. G., *Captain and Assistant Surgeon.*—Granted leave of absence for four months, on Surgeon's certificate of disability.—*S. O. 219, A. G. O., September 20, 1882.*

BUSHNELL, G. E., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for one month.—*S. O. 147, Department of Dakota, September 7, 1882.*

HOPKINS, W. E., *Assistant Surgeon.*—Relieved from further duty at Camp Washington, Gaithersburg, Md., and will proceed to Fort Adams, Rhode Island, and resume his duties at that post. —*S. O. 168, Department of the East, September 22, 1882.*

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

ORIGINAL LECTURES.

IRITIS.

A Clinical Lecture delivered at the Central Dispensary, Washington, D. C.

BY SWAN M. BURNETT, M.D.,

SURGEON IN CHARGE OF THE DEPARTMENT OF DISEASES OF THE EYE AND EAR.

(Reported for THE MEDICAL NEWS.)

GENTLEMEN: The cases which we now present to the class, represent a form of eye disease which should be of great interest to you, from both a practical and a scientific standpoint. It demands your attention practically, because of its frequent occurrence and the disastrous results which usually follow it if not promptly recognized and energetically treated; while its scientific importance consists in the fact that we have represented in it all the forms of inflammatory action with which we have to deal, and that too in a position always open to inspection. In other words, the iris is a mirror in which we may see reflected all varieties of inflammation, except the distinctly mucous, from their beginning to their ending.

This is due to the position of the iris and its anatomical structure. Being at the bottom of the anterior chamber, and covered by the clear aqueous humor and transparent cornea, all alterations are readily detected; while in its substance we find all the tissues of the body except cartilage and bone. Muscular tissue is represented by the sphincter and dilator pupillæ; there is connective tissue, and an abundant supply of vascular and nervous elements. The epithelium on its anterior surface being a continuation of that of the posterior surface of the cornea, forms what is, to all intents and purposes, a serous membrane. Besides these, it has on its posterior surface pigment-cells, which bring it by continuity of tissue in immediate relation with the uveal tract in the posterior chamber of the eye, composed of the ciliary body (ciliary muscle and ciliary processes) and choroid. It thus becomes, as you see, a connecting link between the two chambers of the eye, and pathological alterations of each are likely to manifest themselves in it in some form or other, and, on the other hand, morbid changes in its tissue are liable to extend themselves in either or both directions.

From the standpoints of pathology and differential diagnosis, this is of immense advantage. It enables us to do that which I do not think can be done in any other portion of the body so readily; namely, make a precise nomenclature according to pathological products. We should, therefore, expect an inflammation of the iris to assume a purulent, or a plastic, or a serous form, and, as a matter of fact, we usually find iritis appearing under one or the other of these types, though it is by no means rare to have a mixture of two. We may have the plastic supervene on the serous, and sometimes some suppurative action is associated with the plastic, but it rarely or never happens that the serous and suppurative are combined in the same case. There is another form of exudation which is typical and distinct, the like of which has not been found, as far as I know, in any other organ, and that is what is known as the spongy exudation.

Basing, then, our nomenclature on the character of the inflammatory exudation we have: (1) *plastic iritis;* (2) *suppurative iritis;* (3) *serous iritis;* and (4) *spongy iritis.*

Making abstraction of hyperæmia of the iris, which is only the early stage of some form of iritic inflammation—but which oftentimes goes no further—you can class all forms of iritis under one of the above types.

Though these several forms have, in addition to their pathological exudations, some points in their clinical history which serve to distinguish them from each other, there are still some other features which they have in common, to which we will call your attention before we notice the individual types.

In the first place, among the subjective symptoms, we note *pain.* In all forms of iritic inflammation, except the serous, pain is a prominent and important symptom. It is that usually which drives the patient to the surgeon. If one has mere redness of the eyes, unaccompanied by acute pain, it is apt to be referred to a "cold," and professional advice is not sought; but, fortunately for our patients, pain is considered an alarming symptom, and the most intelligent of them at once call the attention of their medical attendant to their trouble. And just here we would call your attention to a very humiliating fact. In a much too large number of cases, unless the medical attendant has taken the pains to inform himself on these questions, the affection is still looked upon as a "cold," and, being considered a mere conjunctivitis, an astringent collyrium is ordered, and the treatment continued for days it may be, whereby much valuable time is lost. Now this is a mistake which should never occur, and no man should engage in a general practice where such cases are liable to fall under his care without being able to make a differential diagnosis between iritis and conjunctivitis. Any neglect in this matter is nothing short of criminal, and if you learn from this clinical course nothing else but to differentiate these two forms of inflammation, you will not have spent your time in vain.

You will remember that in our clinical lecture on conjunctivitis, I called your attention to the character of the discharge in making the diagnosis of this affection. Conjunctivitis being an inflammation of a mucous tissue, has a mucous or purulent exudation. During the stage of hyperæmia, it is true, this discharge may be scanty or absent, but during the state of inflammation proper there is always some mucous discharge. The amount varies from a quantity just sufficient to gum the lids together during the night's repose, to a drachm in the course of a few hours, as we have it in the purulent form. Even an experienced surgeon cannot always tell by the appearance of the conjunctiva whether there is a conjunctivitis associated with an episcleritis, as we find it in some forms of rheumatic ophthalmia, or a mild iritis, and even in some cases of iritis there is sufficient conjunctivitis to give a gumming of the lids on awakening in the morning. The characteristic discharge of iritis is watery. It is simply an increased flow of tears brought about by reflex action through the fifth pair of nerves.

The character of the pain is another point on which the diagnosis hinges. In conjunctivitis it is seldom acute, and assumes more a feeling of discomfort, and as if a foreign body was in the eye, is not as a rule paroxysmal, and is not disturbing at night. On the contrary, the pain in iritis, as each of the patients here present will tell you, is excruciating at times, though there may be periods of comparative repose. The pain too

is usually worse at night, and in the large majority of cases the exacerbations occur during the early hours of the morning. Moreover it is not usually limited to the eye, as is the case with conjunctivitis, but extends throughout the divisions of the fifth pair of nerves on that side. The pain is as often referred to the occipital branch of the fifth as to the frontal.

There is also more or less *photophobia*, or intolerance of light. It seldom or never, however, becomes so excessive as in corneal inflammation, and in some cases is entirely absent. In conjunctivitis, as a rule, unless the light is very intense and artificial, no special discomfort is felt.

In these cases of doubt, the safe rule for the general practitioner, who is not sure of his knowledge, is to instil a drop of a solution of sulphate of atropia into the affected eye. If it is a case of acute conjunctivitis, the atropia, on account of its anodyne properties, will do good, and if it is a case of commencing iritis, it is a strong blow at the enemy at the outset. If the pupil dilates *ad maximum*, leaving only a narrow black line of the iris visible at the circumference of the cornea, the absence of any serious inflammation of the iris can be considered as established. But if the pupil does not expand freely, and particularly if it is oval or irregular in outline, even if no adhesions are to be detected, it would be well to continue the atropia, for the probabilities are that you have to deal with a hyperæmic condition of the iris which may go on to a full-blown inflammation, and the great advantage you have gained in this dilatation of the pupil should not be lost.

We had an instance of this in the condition of the left eye of one of the patients, the colored man Ferguson, before you, as some of you may remember who saw him when he first came under observation four or five weeks ago. At that time there was considerable pain and watering of the eye, with the characteristic circum-corneal zone of redness. The pupil was still active, though less than normal, to the influence of light, and was altered but little in its appearance; in other words, all positive evidence on the part of the iris itself of pronounced inflammation was wanting. But the other manifestations, as well as an undoubted syphilitic history, convinced me that there was a hyperæmic condition which had not yet gone on to the stage of exudation. I therefore ordered a drop of a four-grain solution of atropia to be instilled into the eye three times daily. At his next visit the pupil was dilated, but not to its fullest possible extent, as would have been the case if it had been conjunctivitis, nor was it perfectly round, a somewhat larger bridge of iris showing at the upper outer corner. The syphilitic treatment, which had been previously ordered, and the atropia were continued. Nothing more was seen of him for three weeks, when he returned. He states that in a few days, under the treatment ordered, the pain and redness disappeared and the medicine was stopped. A few days ago, however, all the former symptoms reappeared suddenly and greatly increased in intensity, and when he presented himself an aggravated form of plastic iritis was evident at a glance. Undoubtedly hyperæmia of the iris can be occasionally aborted, as in this case, but the instances are, unfortunately, rare.

We will now take up the individual forms of iritic inflammation and point out the peculiar characteristics of each. As it is the form most commonly met with, I shall consider *Plastic Iritis* first. As its name indicates, the exudation in this form is plastic, and as a result we should expect adhesions between adjacent structures, and this we find to be the case. When the pupil is of normal size the posterior surface of the iris in its immediate vicinity lies against the anterior capsule of the lens. If now, plastic matter be thrown out from the inflamed iris, these two surfaces become adherent, the iris is bound down, and expansion of the pupil at that portion is impossible. If the whole circumference of the pupil is thus adherent, it will be immovable, even on the application of the strongest mydriatic. If, however, only a segment is bound down, a mydriatic will exert some, though it may be not a full, influence on the remaining portion of the iris, and draw the edge of the pupil away from the centre. In this case the shape of the pupil will be irregular. If you take a lens of three inches focal distance, and concentrate the light from a lamp upon the pupil of an eye suffering from plastic iritis, as you see me do in the case—Ferguson—before us, you will note the outline of the pupil, instead of being round and regular, to have one or more reëntrant angles; and if you examine closely, you will see that the apex of each of these angles is a point of adhesion between the iris and capsule. In this case you observe two such adhesions, one at the upper outer angle and another at the lower outer angle. Moreover, if you examine the area of the pupil closely, you will see several small deposits of pigment on the surface of the capsule. These are caused by the pigment from the posterior surface of the iris which remained behind when the iris tissue was torn away from its adhesion by the force of the mydriatic. You will also notice a great change in the appearance of the iris. On comparing it with that of the other eye, you see that it has lost its brilliancy; it is dull and muddy in appearance, and is thickened and spongy-looking. Its radiating fibres are no longer to be seen as in the healthy eye. In this case you notice that the thickening is greater in some parts than in others, and occasionally you will find, as in the case of the soldier from the Soldiers' Home, which we showed some of you last week, a quite clearly circumscribed elevation not unlike a gumma, which, in the majority of cases, it really is. These alterations in the aspect of the iris are due to two causes: engorgement and infiltration of the iris tissue, and inflammatory exudation into the aqueous humor. In certain diffuse opacities of the cornea, the iris has the same muddy and lack-lustre appearance as in iritis, and I have known beginners in ophthalmology to confound the two; but if, when examining by the oblique light of the lens, you carefully note the appearance of the cornea, you need not fall into any such error.

In *Suppurative Iritis* the appearances of the iris are somewhat different. There is great swelling of the tissues, and there is a yellowish tinge to the whole, due to the purulent infiltration, and nearly always there is pus in the anterior chamber, which by the force of gravity falls to the bottom, forming what is known as a *hypopyon*. As there is always a greater or less amount of plastic matter thrown out, we may look for some adhesions, but the infiltration of the tissue is so general that the mydriatic seldom produces any effect.

In *Serous Iritis* we have a totally different set of symptoms and appearances. In this type there is little or no pain, and not usually any signs of acute inflammation, such as redness, photophobia, etc. Patients, as a rule, come for examination on account of defective vision only. A superficial inspection of such an eye does not usually offer any explanation of the complaint. It is here that examination by the oblique light, as you saw me make it in the case of Ferguson, is of essential service. On concentrating the light from the lamp by means of the three-inch lens, on the cornea and iris, you will find that the cornea, while almost perfectly clear for the greater part of its extent, is studded on its posterior surface over a certain area with fine dots like the dust of meal. This area is usually at the centre of the inferior part of the cornea. You will find a statement in the text-books to the effect that these dots are arranged in the form of a pyramid with its apex upward, and this form is accounted for by supposing the

greater quantity of the matter forming the dots has fallen by the action of gravity towards the bottom. According to my observation, this is by no means the rule. In a very large number of cases the affected area occupies the centre of the cornea, and is not pyramidal in shape, and you can quite frequently see a clear portion between the corneal periphery and the lower portion of the affected part. These dots vary in size from those which can be readily detected by the naked eye, to the most minute ones only visible by means of a magnifying glass. The iris tissue seen through the clearer parts of the cornea is but very little if at all altered, and the pupil, instead of being abnormally small, is, on the contrary, frequently somewhat dilated. The question now naturally arises why this should be called iritis at all. Formerly it was not. In some of the older text-books it was called *Descemitis* and *keratitis punctata*, but there is as little evidence of an inflammation of the cornea proper as of the iris. We seldom or never have an implication of any portion of the cornea except the membrane of Descemet. But we do sometimes have the deeper structures of the iris involved, though, as a rule, the morbid process is limited to the epithelium on the anterior surface, which is, as I have told you, continuous with that lining the posterior surface of the cornea. In fact this layer forms a continuous lining to the cavity of the anterior chamber, and when it is affected in one portion, it is likely to be affected in another. I am, therefore, not of those who look upon the dots on the membrane of Descemet as altogether deposits of inflammatory matter thrown out by the iris. The whole affection is a morbid process confined to the epithelium lining the aqueous cavity, embracing the cornea as well as the iris; and although some of the dots may be due to fibrin which has been deposited by the aqueous, much the larger number are due, in my opinion, to degenerative changes in the cells themselves. It has been called serous iritis because there seems to be an unquestionable increase in the liquids in the interior of the eye, as evidenced by an increase in the tension of the eyeball and of the depth of the anterior chamber in a very large number of instances. It is by no means infrequent to see a plastic form of iritis engraft itself on a serous. In such a case, you will have the signs and symptoms pointed out under that head.

The next form of iritis which I shall consider, I am enabled to illustrate with a case. It is rather rare, and was not described until within the last eleven years. I allude to *Spongy Iritis*. As its name implies, the exudation in this form is spongy, and it fills the whole of the anterior chamber. The appearance is quite peculiar and distinctive. The iris itself is almost obscured from sight, and a superficial glance might lead you to suppose a diffuse keratitis. The color is of a yellowish-gray, and in the early stages perfectly uniform, which is hardly ever the case in keratitis. It is, however, when the exudation is beginning to be absorbed, as it usually does in the course of a few days, that this character is most marked. The case before you, of Margaret G., a colored woman, aged 20 years, will show you this quite distinctly. On throwing the light from the lamp into the eye by means of the lens, you will see that the lower part of the anterior chamber is of a grayish-yellow color, and the iris is scarcely visible; you will notice, too, that the surface of the cornea is unaffected; you will observe at once a sharp line running across the cornea, about three mm. from the upper edge, and beyond this you see the iris quite clearly, and but little altered in structure. If I now cause the patient to look strongly downward and still keep the light concentrated on this portion of the cornea, you will see that this line marks the boundary of an exudation which occupies the depth of the lower portion of the anterior chamber from the iris to the cornea. The course followed by this exudation is quite regular, and the clinical history of such cases offers some typical deviations from the usual plastic form. In the first place, the pain in the earlier stages, before the exudation begins to be observed, is greater than we usually find it in the ordinary plastic form, and it is more continuous, having no periods of remission; but the cessation of pain, according to my observation, is almost instantaneous as soon as absorption begins. The manner of absorption, too, is peculiar. It begins at the circumference and progresses towards the centre from all sides, presenting always the sharply defined edges which I show you in this case. Such an appearance is very likely to lead to the supposition of a lens dislocated into the anterior chamber. The absorption progresses gradually, but with comparative rapidity, and usually in a week or ten days there only remains a small quantity of a gelatinous-looking material in the pupillary area.

The case before us is exceptional in so far as it is a woman, the only cases which have been reported in detail thus far being in males.

It sometimes appears under a typical form, and when the exudation is absorbed you find no adhesions. In Margaret G., however, it is associated with iritis plastica, and you can see behind the grayish exudation, if you look carefully, what I am sure is a gumma at the lower inner edge of the pupil.[1]

The character of this exudation is distinctly fibrinous in its early stages, but it seems to possess no tendency to organization and becomes wholly absorbed, first breaking down into a gelatinous mass.

But iritis, gentlemen, can be very properly and advantageously studied from another standpoint, namely, that of causation. We may have an etiological nosology, and its practical advantages are not to be overlooked. Considered in this light, experience has taught us that we may divide inflammations of the iris into the following classes:

1. Idiopathic iritis.
2. Syphilitic irits.
3. Rheumatic iritis.
4. Traumatic iritis.

Idiopathic iritis is of course only a form of expression to hide our ignorance of the cause of the inflammation. When we can find nothing to account for it, we say it is idiopathic, and genuine cases are probably rare.

The *syphilitic form* is, however, of frequent occurrence. The number of cases of syphilitic iritis probably outnumbers all the other varieties, even after we have eliminated those of doubtful character. It usually occurs under the plastic form, though the serous and spongy forms are by no means rare. It is, however, doubtful whether syphilitic iritis ever assumes a suppurative character. The tendency of the syphilitic lesion is more towards organization than pus formation.

Are there any characters, aside from a history of infection, which stamp an iritis as of specific origin? There are many who contend that there are. The point on which most stress is laid is the circumscribed character of the inflammation.

In syphilitic iritis, as in all other forms of specific inflammation, it is held, the tendency is to a strict circumscription of the pathological product. You will observe that in the papillary eruption on Ferguson's forehead, each papule is distinct, and however close two may be together, there is no appearance of their running into each other. While, therefore, not accepting this appearance as pathognomonic, it often serves as one point in a differential diagnosis, particularly be-

[1] After the exudation had been absorbed, as it was in a week from that time, the nodule and an extensive synechia were found. A clear history of syphilis was given.

tween syphilitic and *rheumatic* iritis. In the latter form I think it is seldom that there is such a restriction of inflammatory action to a particular portion of the iris tissue. You know the character of rheumatic inflammation in other parts of the body is diffuse, and it never becomes distinctly limited in outline.

As compared with the *rheumatic form*, syphilitic iritis is of short duration and comparatively easy to manage if seen sufficiently early. I know of no other internal inflammation of the eye in which the influence of proper treatment is so promptly manifest as in syphilitic iritis. In from five to fifteen days the force of the disease can usually be broken, while in rheumatic iritis sometimes weeks pass with no perceptible change, and in a large number of cases of the typical form the regulation "six weeks" go by before you can declare the patient convalescent; and in this form I think relapses are more frequent than in the others. I am convinced too that the pain in the rheumatic variety is more persistent and more severe than in any of the other forms.

You may have iritis occur at almost any stage of syphilis, though it is commonly reckoned among the secondary symptoms. I have seen it several years after infection, while again it may be the first prominent symptom to attract attention. In fact, it would never be well to conclude too hastily that a case is not of specific origin, even if there be no history pointing to syphilis. The old soldier from the Soldiers' Home, already alluded to is a case in point. As soon as I saw the nodule on the pupillary edge of the iris, I asked the assistant surgeon of the Home who had had him under observation for several weeks, if there were no symptoms of syphilis. He said the most thorough examination had failed to reveal any trace of past or present lesion of that nature. I advised him to continue his watch, for I was quite sure the nodule was a syphilitic gumma. Two weeks afterwards he informed me that typical mucous patches had made their appearance in the mouth.

I shall not speak separately of gonorrhœal iritis, because when we have iritis as an accompaniment of gonorrhœa, it is always associated with the rheumatism which we sometimes find attendant upon urethral discharges.

Traumatic iritis, more frequently than any of the other varieties, manifests itself under a purulent form, particularly when the wound is caused by the entrance of a foreign body. You will remember the case of the colored man from the country, admitted to the house some two weeks ago, who had, when we saw him only two days after the injury, a pronounced purulent iritis. The foreign body (a piece of steel from a hoe) must have been very small, for the wound in the cornea was discoverable only by oblique illumination, and the injury to the iris seemed to have been proportionately small. There was already pus in the anterior chamber, forming a hypopyon, and the iris tissue was swollen and of a yellowish tinge. With a view (though without much hope) of checking the progress of the inflammation, we opened the anterior chamber, let out the pus, and excised the wounded portion of the iris. It was of no avail, however, for the next morning the lids were swollen hard and tense, and there were all the signs of panophthalmitis. The case went on to atrophy of the globe, and a few days ago we enucleated it, because it was still painful, and the other eye began to show signs of irritation. In this case the inflammation travelled back to the ciliary body and choroid, and the foreign body, which was still in the interior of the eye, no doubt added greatly to the virulence of the inflammation.

As a rule iritis is unilateral, though both eyes are liable to be affected in time. I have not observed that the prognosis is worse in the colored than in the white race.

Treatment.—The first object in the treatment of iritis is to obtain the widest possible dilatation of the pupil and maintain it. It is above all things important to prevent adhesions between the iris and capsule, and this is much more likely to occur when the pupil remains contracted. In the first place, when the pupil is dilated, the iris is removed further from the capsule, making adhesion more unlikely; and, in the second place, the area to be filled with inflammatory exudation is largely increased, and the danger of occlusion of the pupil is correspondingly reduced. This dilatation of the pupil is best obtained by instilling into the eye every six hours a solution of sulphate of atropia of the strength of four grains to the ounce of water. The atropia being an anodyne, also acts as a calmative to the pain. It acts, too, directly on the inflammatory process, for in dilatation of the pupil the iris tissue is compressed and of course holds less blood, and as a consequence the exudative process is in a greater or less degree checked. All other treatment is secondary to this. When we see cases of iritis for the first time, the inflammation has usually made such headway that it is useless to attempt to cut it short; but when the pain is excessive and the inflammation of a distinctly sthenic type, local blood-letting is advisable. From three to six leeches to the temple or the artificial leech will often give immediate relief to these symptoms. But for the relief of pain the most reliable remedy is opium in some of its forms. It is often advisable to give the patient an opiate on going to bed—usually as late as ten or eleven o'clock, since the severest pain is commonly felt in the early morning. The opium not only subdues the pain, but acts beneficially on the course of the inflammation. After a full dose of the drug, the injection and photophobia are usually much less. As regards local applications for the relief of pain, nothing is better than warmth and moisture in some form. The most agreeable and convenient manner of its application is by means of a flannel bag about the size of the hand, filled with hops, which is immersed in water as hot as can be borne, and laid on the eye after it has been squeezed so as to expel all superfluous water. It was formerly the custom as soon as a diagnosis of iritis was made out, to begin the use of mercury, and push it rapidly to salivation. The pendulum then swung in the other direction, and there were those who found they could treat iritis, even of the specific form, without any mercury. The proper course lies between these two extremes. In rheumatic iritis mercury seems to exert but little influence on the course of the inflammation, but large doses of salicylate of sodium quite often make a profound impression on it, and in some cases may be expected to cut it short. But it must be given very heroically—as much as thirty grains every three hours until there are giddiness and singing in the ears. Where, however, there is reason to suspect syphilis, even though no positive proof of its existence may be furnished, mercury should be given. It need not be used, however, to the extent of immediate salivation. I am among those who believe that the action of mercury in syphilis is to assist nature in disposing of the excess of cellular elements to which the specific poison has led. This seems to be accomplished by a breaking down or fatty degeneration of the cells, with elimination by the various emunctories. In this process mercury undoubtedly aids, and I think the more effectually when given in moderate doses for a considerable time. Among our out-patients we generally use one-thirty-second to one-sixteenth of a grain of bichloride of mercury with two or three grains of iodide of potassium three times daily, after meals.

There is usually no necessity for confining the patient

to a dark-room. A modulation of the light is all that is requisite. Completely darkened chambers in eye inflammations are among the barbarities which have come down to us from the dark ages of ophthalmology. If all light is positively painful, then the bandage may be applied to exclude it, but we have no right to deprive the other portions of the body and the patient's attendants of the beneficent influence of that stimulant of nature so necessary for the mental and bodily well-being.

In the treatment of the serous form, where there is no pain and but little inflammation, the atropia, opium and other palliative measures may be dispensed with. Here our chief reliance must be on mercury, continued in small doses for a long time, as the course of the disease is usually very tedious, sometimes running over many months.

By CHARLES STEDMAN BULL, A.M., M.D.,

SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; OPHTHALMIC SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN, AND TO THE NURSERY AND CHILD'S HOSPITAL; LECTURER ON OPHTHALMOLOGY AND OTOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

Though the application of electrolysis in the treatment of vascular growths is by no means a new thing in surgery, and, although, it has had a somewhat extended trial in small vascular growths or nævi in the eyelids, its application in the treatment of large vascular tumors of the orbit or eyelids, or, in fact, any part of the body, has been limited. The following is, therefore, reported, not only on account of its rarity and the great size of the tumor, but also as demonstrating the advantages and disadvantages of employing electrolysis in the treatment of large vascular growths in the vicinity of the orbit and eyelids. The patient was a female child, who was admitted to the Nursery and Child's Hospital on the 19th of September, 1881, at which date she was twelve weeks old, and I first saw the child one week later. The following information was obtained from the mother: The family history was excellent on both sides. The father and mother are both living and apparently in robust health. The little patient was their first child, and was born at full term, after a very easy normal labor, on June 26, 1881, and has been nursed by the mother from her birth.

She has never had a day's illness, and sleeps quietly and soundly at night. On the second or third day, the mother does not exactly remember which, she noticed a spot about the size of a small nickel cent, half an inch above the centre of the left eyebrow, upon the forehead, and to the right of this, and near the median line, another of the same character, but smaller in size. These two spots were but very slightly or not at all elevated above the surrounding surface, were very *white* as compared with the surrounding skin, but there was no swelling or roughness of the skin noticeable. The child grew rapidly, but the spots remained unchanged for a period of three weeks, and nothing abnormal was noticed for the same period, when there appeared a slight discharge from the left eye, as if the child "had caught a cold in the eye," which was muco-purulent in character, as the eyelids were glued together at times. Though this was treated with astringent applications by a physician of the neighborhood, the eye did not improve and the discharge continued. About the same period, or three weeks after birth, a small, vivid red spot, as large as a pea, appeared upon the lower anterior surface of the right forearm, and has slowly increased in size. The upper eyelid now began to have a swollen appearance, and partially concealed the eyeball, and about this time the two spots began to grow red, not suddenly, but very gradually, and this was accompanied by an extension of the swelling from the eyelid upwards and forwards. During the next five weeks there was an occasional cloudy, watery discharge from the eyelids, and the swelling of the upper lid and supra-ciliary region became more prominent. The area of redness spread somewhat rapidly over the whole eyelid, upwards upon the forehead, and slightly upon the temple at the external commissure of the lids. During the three weeks preceding the child's entrance into the hospital, the tumor increased in size very rapidly upwards, outwards, and inwards towards the nose, as well as forwards, giving a marked prominence to the growth in the supra-orbital region, and to some extent filling the zygomatic and temporal fossæ. The mother also noticed that the child could not lift the upper lid, that the eye was pushed very decidedly forward, and was very limited in its motions. The area of redness was always progressive, but not to the same degree in all directions, the main extension having been upwards upon the forehead, "in two tongues," as the mother expressed it. It also gradually changed from a light-red or pinkish hue to a reddish-purple color.

When I first saw the child, she was a very marked example of perfect health in every particular, except the left eye and vicinity. A careful examination revealed the following condition of affairs. The swollen and purple eyelids projected almost directly forwards, in front of the plane of the orbit, in a mass as large as the two closed fists of the child, so that in a profile view of the face, it concealed the entire nose except the tip. The lower lid was entirely hidden from view by the overhanging upper lid, which was pushed downward much below the level of the lower orbital margin, and about on a plane with the junction of the nasal cartilages with the naso-buccal furrow. The swelling extended over the entire upper lid, upon the bridge of the nose, and encroached upon the right side of the nose and nasal end of the right eyebrow. The child's forehead was rather prominent, and the swelling extended well above the frontal bosses. The growth also filled the entire zygomatic fossa and nearly the entire temporal fossa, extending backwards to the anterior edge of the concha. Most of the swollen region in the lid and on the forehead was of a livid red or purple, but the inner or nasal end of the lid was much lighter in color, and the temporal region was scarcely discolored. From the supra-ciliary region there extended up-

wards two irregularly shaped tongues well towards the line of the hairy scalp, which were much brighter in color, and resembled strongly in appearance the ordinary vascular nævus. The ciliary margin of the lid, while almost purple in color, was but little swollen, and there exuded from beneath it a thin, muco-purulent discharge. The skin over the swollen region was tense except at one point, the most prominent of all, which was situated over the line of the superior orbital margin, and at the union of the middle and inner thirds of the lid. Here the skin fluctuated on pressure and was evidently very thin.

Careful examination showed that the main swelling was in the subcutaneous tissue of the lid and eyebrow and in the orbital cellular tissue, while the skin itself was the seat of a pure nævus. The growth in the zygomatic and temporal fossæ, though yielding slightly to pressure, was firm and dense, but the swelling in the lids and orbit yielded markedly to pressure, and a few moments' compression with the fingers directly backwards towards the apex of the orbit sufficed to diminish the size of the tumor by from one-half to two-thirds. The moment, however, that the fingers were removed, the swelling reappeared as before. On lifting the upper lid, the eyeball was seen to be pushed downwards and inwards toward the nose, but there was little protrusion of the eye beyond the normal plane of the orbital opening, showing that the orbital part of the growth did not extend deeply into the orbit, but rather occupied its upper and outer portions, and this latter fact could be recognized by introducing the finger beneath the upper lid at the external canthus. The eye was limited in motion in all directions, but especially upwards and outwards. The media and membranes were perfectly normal, the iris reacted naturally, and an ophthalmoscopic examination showed a normal nerve and retina with no change or interference in the pupillary circulation. Close observation of the summit of the growth discovered a slight pulsation visible to the eye, and this became more distinct to the fingers when a slight pressure was made upon the tumor.

The thinning of the skin over the summit of the tumor and its easy indentation at this point, convinced the writer that there was a cavity of some size in this region, which probably was entirely outside of the orbital cavity, and was filled with blood; and that therefore the tumor was of a mixed nature, cavernous as well as teleangiectatic, in this resembling so many vascular tumors not only of the lids but of other parts of the body. A vessel as large as a large goose-quill could be felt under the skin, at the external angle of the lids, and could be traced a short distance towards the temple, and another one, somewhat less in size, was felt running across the bridge of the nose and connecting with the angular artery on the right side; this was distinctly an artery, as it pulsated under the finger. Pressure upon one or both of these vessels made no difference in the swelling. Pressure upon one or both carotids produced no effect on the size of the tumor, even when kept up for some time, but it stopped all pulsation. At no time was there any murmur or bruit noticeable over the tumor or vicinity. The child was very restless during this long examination and cried persistently, but became quiet immediately when left undisturbed. Some bleeding from beneath the eyelids followed, but it was slight in character and ceased in half an hour.

Another point determined by the examination was that the pressure of the tumor had produced an absorption of the underlying bone in at least two places; for just over the supra-orbital margin, in a line with the point of exit of the supra-orbital nerve, was a distinct excavation in the bone into which the point of the finger could be introduced, and at the external angle of the orbital margin was another and larger excavation. The skin over that portion of the tumor occupied by the two tongues before mentioned was corrugated both to the sight and touch, and all over the growth, in detached spots, there was a well-marked superficial arborescent vascularity. The nævus upon the fore-arm was about the size of a silver ten-cent piece, with elevated surface and sharply defined outline. There were no other marks anywhere else upon the child's body.

A consultation was held by all the members of the attending and consulting staff, all the gentlemen but one agreeing in their opinions as to the nature of the tumor, but differing somewhat as to what ought to be done. One of the gentlemen, however, differed from the opinion of his colleagues that it was a mixed teleangiectatic and cavernous growth, and thought that it might be malignant in character. The methods proposed for the relief of the child were, with one exception, of the same nature, and differed only in detail. The first thing to do was to cut off the blood supply in one of several ways. The majority were in favor of ligating the left common carotid in the usual way. Another suggestion was to tie both the external and internal carotid arteries on the left side. Still another was to ligate both common carotid arteries, because the tumor extended somewhat beyond the median line, and evidently drew some of its vascular supply from the vessels on the right side of the face, and also because of the possible internal anastomosis within the orbital cavity through the medium of the ethmoidal vessels. This

proposition was abandoned, because it left the supply of blood to the head to be carried on only through the medium of the vertebral arteries, and in an infant these vessels are very small and probably of insufficient size for the nourishment of the parts. It was thought that the left common carotid artery at least should be tied, as a preliminary step, and that afterwards, in case there was but little diminution in the size of the tumor, an operation might be undertaken for ligating any smaller vessels around the base or outskirts of the mass.

It was the opinion of most of the gentlemen who saw the case that electrolysis was not to be thought of as a primary or preliminary operation, owing to the extreme size of the tumor, and also to the probability that it was a mixed cavernous and teleangiectatic growth; but that after the carotid artery had been tied, and the child recovered from the operation, electrolysis might be essayed as a further help in bringing about coagulation and diminishing the size of the tumor. From all these opinions the writer ventured to dissent. He was of the opinion that the child was too young to allow of any hopes of a successful result from ligation of the common carotid artery, as death would probably ensue. The operation of ligating the nutrient vessels at the base or periphery of the tumor he thought too dangerous to be justifiable without previously tying the common carotid. He was strongly inclined to try electrolysis as a primary operation, as the least dangerous in the case, while it might produce at least a partial result in lessening the size of the tumor. It was finally decided to keep the child under observation in the hospital and await further developments, and to give the child five-drop doses of the fluid extract of ergot three times a day, as a possible means of controlling the circulation.

The child remained under observation until the end of December, and during the first month of this period the tumor slowly increased in size, and the skin over the palpebral portion seemed to grow thinner, but about the fifth week after the administration of the ergot had been begun, the growth seemed to stop and the tumor remained apparently stationary in size for several weeks, then it began to slowly diminish in prominence, and this continued until the end of December, when the mother was permitted to go home with the child upon condition that she would return immediately if any change for the worse appeared. During all this time the ergot had been constantly administered, and the mother was directed to continue its use at home.

The child was not seen again until the middle of March, 1882, at which time the tumor had again increased very much in size, and the anterior skin wall was extremely thin. The mother had neglected the ergot treatment, and there had been recently several small hemorrhages, which apparently came from beneath the surface of the lids, and frightened the mother very much. There was no change whatever in the child's general condition, and after a week's observation, it was not deemed advisable to postpone operative interference any longer. As at the first consultation, so now, the writer determined on electrolysis, as perfectly applicable to a soft growth which contained a decomposable liquid, whether arterial or venous, or both. It was thought that the decomposition of the blood and the accumulation of acids and alakalies at each of the poles, would bring about a chemical cauterization in the walls of the bloodvessels. This would probably aid in the disintegration and absorption of the tumor. There would be little or no danger from hemorrhage, as the coagulation would be instantaneous around the needle punctures, and the only danger to be feared would be a possible suppuration and abscess in the tumor, ending in perforation of its anterior wall. We know that this electrolytic action is most pronounced at the cathode, and that absorption is hastened by the chemical effects of the current and the mechanical and irritating effects of the needles, and that this may slowly continue for weeks. As a result, disintegration and atrophy take place, which continue for a long time after all electrolytic treatment has ceased. Another fact which inclined the writer strongly to electrolysis, lay in the knowledge that we have that an erectile tumor offers but little resistance to the passage of the galvanic current, and its tissue readily electrolyzes. Furthermore, in vascular tumors both poles of a galvanic battery may be made to operate simultaneously.

The first application of the electrolytic method was made on March 28, 1882, the child having previously been etherized. The battery first employed was a zinc-carbon Stöhrer battery; and on the principle that definite electro-chemical action may be excited when either one or both electrodes are broad flat disks, the first operation was done with the needle at the negative pole and a flat sponge disk at the positive pole. The needle was plunged through the skin into the tumor at the external angle of the orbit, and the sponge or positive pole was at first placed over the swelling in the temporal fossa. The current from two cells was then passed through the tumor, and, after one minute, increased to four cells, and after another minute to eight cells. At the end of the third minute the positive pole was removed from the temporal fossa and placed over the superior orbital margin, just covering the thinnest part of the tumor wall. The number of the cells was then gradually increased to sixteen, and after six minutes had elapsed from the time the current was first allowed to pass through, it was broken. A small nodule of condensation was felt around the negative pole, and the needle was withdrawn with some difficulty. Time, six minutes; current from sixteen cells. The child rapidly regained consciousness, and in less than ten minutes was laughing and crowing in its mother's arms. There was no perceptible change produced in the tumor by the operation. and no general rise of temperature or any untoward symptom in the general condition of the little patient.

On April 1st, the third day after, the second session was held. The child was etherized as before, and the needle or negative pole was inserted about half an inch from the previous point of in-

sertion, and just over the superior orbital margin. The positive pole or moist sponge disk was applied to the nasal end of the tumor, and a current from two cells was then passed. The number of cells was slowly increased to sixteen, and the positive pole was slowly moved about all over the inner or nasal half of the tumor. This second session lasted twelve minutes before the current was broken. As before, a quite marked nodule of condensation was felt at the negative pole, and the needle was removed with some little difficulty, and was followed by two or three drops of almost black blood. The child regained consciousness rapidly, and its general condition was apparently entirely unaffected either by the etherization or the operation, there being no rise of temperature or acceleration of the pulse. Time, twelve minutes; current from sixteen cells.

The third session was held on April 7th, six days later, and a different battery was employed, being a modification of the ordinary zinc-carbon battery by Spamer. The battery fluid used was composed of bichromate of potassium, 20 grammes; sulphuric acid, 45 grammes; sulphide of mercury, 2 grammes; and distilled water, 300 grammes. As electrolysis is produced most quickly and effectually when the current is made very dense by the use of small needles, it was determined to use small needles at both poles. The negative pole was introduced into the tumor on the nasal side, just at one side of the bridge of the nose and below the inner end of the eyebrow, and the positive pole was introduced on the temporal side near the external angle of the orbit, and just above it. As at the other sessions, the operation began with a current from two cells, and this was gradually increased to eighteen cells. The distance between the points of the needles was about half an inch as nearly as could be determined. Marked condensation occurred at the negative pole and a somewhat slighter hardening at the positive pole, but there was no perceptible diminution in the size of the tumor. Both needles were withdrawn with some difficulty, and their removal was followed by some slight bleeding. The superficial color of the tumor became decidedly paler, and this was also noticeable in the two tongue-shaped nævi, which ran up on the forehead, and lasted for a short time after the breaking of the current. Time, twelve minutes; current from eighteen cells.

The fourth session was held on April 11th, four days later. The negative pole was introduced just below and to the inside of the external canthus, and two needles were attached to the positive pole, one being introduced on the nasal side very near the point of entrance of the positive pole at the previous session, and the second being introduced through the lid lower down. A current from two cells was then passed, and this was somewhat rapidly increased in strength until twenty-two cells had been brought into the circuit. The two positive poles evidently entered a cavity, as they moved freely about, and could be made to rub against each other. The tumor blanched rather rapidly under this current, which was kept up unbroken for fifteen minutes. When the current was broken, the needles at the positive pole were removed without any difficulty, but the negative pole was removed with great difficulty, came out with a jerk, and was followed by some fluid blood, and a good deal of thick, disintegrated blood. Violent reaction followed, with marked increase in size of the tumor, a rise of temperature to 102¼° and pulse of 168, with vomiting, crying and constant restlessness, coming on in about five hours. There was marked and extensive condensation about all three needle-holes, and a perceptible diminution in the size of the tumor. The unpleasant symptoms disappeared on the following day, but the condensation remained and had increased, so that over a space included between the points of entrance of the needles the tumor was hard and firm, and pulsation had ceased. The area of condensation was about an inch and a quarter in diameter, and was of an elliptical shape. Owing to one of the needles having partially lost its insulating envelope, there was a small slough of the skin at its point of entrance, but this proved to be very superficial and there was no hemorrhage at this point. The hardening and condensation increased steadily as long as the child remained under observation, but unfortunately the father removed her from the hospital on the fifth day after the operation, contrary to the expressed wishes and direct orders of the writer.

In conclusion, I have to thank Dr. Chas. T. Poore, and Dr. Beverley Livingston, for the use of their batteries and their kind assistance at the operations, as well as Drs. Henry and Murray, of the House Staff of the Nursery and Child's Hospital.

JULY 26, 1882.

BLOWS ON THE ABDOMEN AND THEIR FATALITY.

BY WOOSTER BEACH, M.D.,
OF NEW YORK.

IN the NEWS of September 16th, are reported four cases of injury to the abdomen, of a severe nature, ending in recovery. Allow me to present a case with a fatal termination:

A young man about twenty years of age, while somewhat under the influence of liquor, created a disturbance in the street, for which he was arrested by a policeman. He became abusive to the officer and refused to be taken to the station-house. The assistance of three other policemen was secured, and the four seized the young man, two taking him by the arms, and two by the legs, carrying him, in this way, through the street. On the way, he was very noisy and struggled some, but was easily controlled, Suddenly, one of the policemen raised his club and struck him a blow, as near as could be ascertained, directly over the stomach. Instantly, he ceased his noise, his body became limp and powerless, and in this apparently lifeless condition, he was carried on to the station-house, a distance of less than a quarter of a mile. Arriving there, it was found that he was dead.

A post-mortem showed the body to be that of a well-developed, apparently healthy man. There were no external indications of violence, and after

a careful and exhaustive search of the entire body, absolutely no abnormal appearances could be discovered. I gave it as my opinion, before the coroner's jury, that death resulted from the blow. The policeman was tried, and convicted of manslaughter.

Because his cases ended in recovery, your contributor argues that blows on the epigastrium cannot produce sudden death.

While I confess to sharing in the doubt as to whether a fatal result can with positive certainty be traced to an injury of this kind, the first two cases reported, seem to me as tending rather to dispel the doubt, than to strengthen it. Had death quickly followed the receipt of the injury, probably no post-mortem changes would have been discernible. Now, who would say that in both these cases, the patients were not in great danger of dying? They suffered from *extreme* shock. Life was at so low an ebb that, for a time, it must have been very doubtful whether they would revive. Both recovered, it is true, but these cases seem to prove that, had the conditions been even slightly changed, the wounds would have resulted fatally. If the constitution of the patients, or the force or character of the blow, or perhaps the treatment, had been different, they might have died. And from these injuries we would not likely have post-mortem marks.

The latter two cases do not bear on the question, as the violence was so great in them that its effect would leave lesions plainly visible after death.

It cannot be claimed that it is the amount of violence to the abdomen that produces sudden death, as this is sometimes so great as to rupture a viscus, and without death immediately following. Shock more or less profound follows, but, as a rule, not sufficiently severe to cause death.

If it is true that a blow on the abdomen does cause death, it must be from some peculiar or unusual manner in which it is struck, or from it falling on some particular spot, or from some other unexplainable reason. It must be admitted that there are but few cases on record of sudden death from this cause, but this alone does not prove them to be uncommon. Cases of this kind would not likely reach a hospital, and its records would therefore show none. If attended by a physician, they would not likely be published, for the reasons that physicians generally do not publish their cases, and that those who do their duty better in this respect, would not be likely to report a case of a class not held to be exceptional by most surgical authorities.

Still, I cannot help agreeing with the writer of the article in the News, that sudden death, following blows on the abdomen, happens very seldom. In an extensive experience in examinations of bodies for the coroner, I can recall no case except the one that I report. Unfortunately, most of my notes have been destroyed, and it is possible that cases escape my memory. I can, however, assert with a good deal of positiveness, that but this single case of a criminal nature has been investigated by me. Further, this rarity seems fairly proved by the fact that in the thousands of fights, beatings, and tussles, besides innumerable accidents almost constantly occurring, there cannot but be numerous instances where blows are inflicted on the abdomen, and, supposing the blow necessary to produce sudden death require ever so unusual or peculiar conditions, considering the vast number of blows given, not an insignificant percentage must perfectly fulfil these conditions. In the aggregate, these would constitute a large number of such deaths, and the knowledge of them could not escape finding its way to the profession.

Yet the well-authenticated evidences of death rapidly following blows over the epigastric region, must be explained in some way. They are usually attributed to their effect on the solar plexus. Without attempting fully to discuss this matter, I merely suggest, first, that it seems improbable that the solar plexus, so thoroughly protected by the soft and movable viscera, and the elastic gas in the stomach and intestines could receive a shock from a blow on the skin over it; and second, that those serious injuries that are sufficiently severe even to rupture abdominal organs do not communicate an impression on the solar plexus. At least, they do not as a rule cause sudden death. The "stroking" and "tapping" experiments of the German investigators should perhaps be considered, but I am not prepared to make an application of the results of their experiments to the solution of this question.

I have repeatedly called attention to a class of sudden deaths of which I find little or nothing in the books. An individual, apparently in perfect health, pursuing his ordinary avocation, with scarcely a moment's warning, sinks to the earth and dies, it might be said, instantaneously. Post-mortem examination conducted with the greatest care, reveals absolutely nothing to account for death. Instances of this mode of death are by no means uncommon. Occurring in private practice, and an autopsy being difficult to attain, the physician certifies to "heart disease" as the cause of death, a term which covers a multitude of sins—of omission. Persons dropping dead in the street, or under circumstances that may be thought suspicious are brought to the coroner's notice and their bodies are subjected to post-mortem examinations. To meet the possible objection that the autopsy in these cases has not been made with thoroughness, or with sufficient knowledge, or skill, I will say that in many of them, I have had the assistance of the best pathologists that our city affords.

Now, in view of the difficulty of finding any reason to explain these deaths following blows on the abdomen, and from the unfrequency of fatal results following such blows, I believe the assumption is entitled to consideration, that they should be classed with the sudden deaths that I have described, and that their occurrence directly after the blow, is a mere coincidence.

This subject is of decided importance in a medico-legal view, and I hope that its discussion may continue and not cease till it is definitely settled whether comparatively light blows on the epigastrium produce sudden death.

161 East Forty-ninth St.

EPIDEMIC CATARRHAL FEVER.

BY FORDYCE GRINNELL, M.D.,
PHYSICIAN TO THE PINE RIDGE INDIAN AGENCY, DAKOTA.

A LATE epidemic of catarrhal fever occurring throughout these regions, presents some points of interest to which it may be well to refer.

But little attention seems to be given in medical literature to the consideration of this disease. Dr. Flint in his *Practice* devotes barely one page to its consideration, and yet it is one of our most widely extended and frequently recurring epidemics, and, furthermore, one seizure by the disease does not afford an immunity from further attacks. It is an ailment not infrequently attended with serious results. The writer since the beginning of his practice, ten years ago, has noted three wide-spread epidemics of the disease, has lost one of his nearest relatives by it, and has known of many deaths.

The beginning of the epidemic here was as sudden as is usually the onset of the disease "La Grippe." It seized with great suddenness, and hence has well been termed "lightning catarrh." The first cases developed about the 20th of March, almost simultaneously with the appearance of "epizoöty" or "pink-eye" among the horses. The first family to which I was called lived seven miles distant in Nebraska. The mother of this family was first taken with the disease, afterward the children, five in number, three boys and two girls, and then the father. All were severely affected and confined to the bed a part of the time. They considered their ailment simple "colds," and did not deem it necessary to send for a physician until the most serious symptoms manifested themselves in the third case, a boy 11 years of age. He had complained but little the previous day, was out of doors and playing with the other children much of the time, ate quite a hearty supper at night, and was dead before midnight. He was complaining, however, of pain in the throat, and was quite hoarse, as was his wont when he had a cold, so that his parents did not consider him dangerously ill four hours before death. The pain in the throat and sense of suffocation, however, increased to an alarming extent, and the boy died gasping for breath near midnight, and less than an hour after the messenger had been dispatched for me.

He had been dead nearly an hour when I arrived and, of course, I can not give a more minute description of symptoms. The family, however, had done all that intelligent nursing could do, and I do not think any of the physician's arts could have saved the patient.

His symptoms were very much like those of the other members of the family, only intensified. Afterward the others experienced the usual course of catarrhal fever, commencing chill, general feeling of malaise, and flashes of heat, alternating with chilly sensations. The temperature usually increased in the afternoon and evening, reaching at such times a temperature of 102°–103°. There was reddening of the mucous membranes of the respiratory organs, in many cases the congestion affecting the Eustachian tubes, and in some afterwards treated, producing intense pain in the ears, eventually resulting in a purulent discharge, especially with children and old people.

During the latter part of March I treated 17 cases (11 males and 6 females). In April I treated 192 cases (104 males and 88 females), and in May 48 cases (20 males and 28 females), or a total of 257 cases.

The nervous system in many of these was profoundly affected. Extreme prostration with some intense pain in the head. Sometimes the frontal sinuses were inflamed, and the seat of the pain located there, especially in those where the coryza was most marked. At other times the pain was of a neuralgic nature, or again pain was complained of in one-half of the head, as in migraine. As before referred to, earache was a prominent symptom with children and old people. We can, perhaps, account for this and the subsequent discharge of pus by the extreme congestion of the mucous membranes of the fauces and air-passages, extending into the Eustachian tubes, and thus pressing upon and affecting the membrana tympani.

Sharp, shooting pains in various parts of the body were not infrequently complained of. Those of the chest and side were apparently as severe as those of pleurisy, and increased on respiration. Aside from the usual flushing of the face, I noticed a peculiarity which I have since seen referred to by Dr. Da Costa in THE MEDICAL NEWS for May 20, viz., an irregular mottling of the skin of the face, neck, and breast. This was so marked in one case that the mother feared that scarlet fever or measles was about to supervene. Profuse perspiration quite frequently occurred, especially at night. Diarrhœa occurred in many cases.

The duration of the disease varied, the average being about one week, but many cases continued two or three weeks. One peculiarity of the disease is a tendency to relapse. After one is up and about, and feels comparatively well, a relapse is liable to occur, not, perhaps, including the same increased temperature, but with the same wandering pains, and general feeling of malaise, with, may be, the distress in the nose and orbits, and irritation in the Schneiderian membrane.

Some who had irritable heart, and others who had not, experienced a very unpleasant palpitation, and were obliged to arise to a sitting posture at night to get relief from dyspnœa. Here seemed to be a symptom corresponding to what the veterinary surgeons called the "thumps" in horses, especially those worked while suffering from the epizoöty were not infrequently affected with such strong action of the heart, that each throb was perceptible, and the horses became wet with perspiration even while standing in the stall.

Another result intimately connected with this, and perhaps arising from it, was that almost all mares with foal, severely afflicted with the epizoöty, aborted. Did this arise from the dyspnœa? A similar tendency occurs with pregnant women who suffer from the catarrhal fever.

Cazeaux says, on page 442 of his work on midwifery, "Though some epidemics (of influenza)

have appeared to spare pregnant women, many have affected them as severely, at least, as other individuals exposed to the same influences. Thus I found, as did also M. Jacquemier at the Maternity Hospital, that the epidemic of influenza attacked a great many pregnant women, but contrary to his observations, I witnessed numerous abortions as a consequence either of the disease itself, or of the violent spells of coughing which tormented the patient."

Zuelzer, in vol. ii. of Ziemssen's *Cyclopedia*, page 535, says: "Pregnant women frequently suffer abortion, and in many who are afflicted with amenorrhœa, the catemenia are established. This effect of influenza has been repeatedly verified in many epidemics. It is, therefore, very worthy of remark, because it recalls analogous phenomena in other infectious diseases, and is indicative of an agency exerting an important alterative effect upon the whole organism."

What is this agency? The effect of the disease is to depress the nervous system, and interfere with the free and full action of the heart. There is, in short, imperfect aeration of the blood, and the blood of dyspnœa induces emptying of the uterus.

Dr. J. Matthews Duncan, in speaking of another subject, says, in his clinical lectures on the diseases of women: "Here I would mention to you an interesting set of facts in connection with this subject. If you read over the cases of heart disease, especially mitral regurgitation, you will find that in them women are very likely to miscarry, and miscarriage is in them almost certainly a direct result of the disease (jaundice).

"If there is a poison in the woman's blood, in this case, it is probably a poison from imperfect aeration of the blood, and that induces the miscarriage. This has been almost proved by experiments on the lower animals, showing that the blood of dyspnœa induces emptying of the uterus. You have further evidence in the fact that the children are almost always born fresh, if not alive. The disease has brought on miscarriage; it has not killed the child. The condition of the blood has stimulated the uterus to action directly."

It seems to me that the abortions in a large percentage of cases are due directly to this—the stimulating effect of deoxygenated blood upon the uterus, and exceptionally, if at all, to the violent spells of coughing referred to by Cazeaux. The cough has been a comparatively unimportant element in this epidemic.

I have noted but one case of premature birth which I attributed to the catarrhal fever. The birth, an easy one, occurred, it was judged, at eight months. The child's face was black, and congested with imperfect circulation, and it died about eight hours after birth. The mother did well.

Of the 257 cases of the catarrhal fever treated, three deaths may be reported as a direct result of the disease, one miscarriage, and three deaths from complications. Two were complicated with whooping-cough, and one with capillary bronchitis. The first case resulting in death I have noted. The second and third were children, one 1½ years of age, the other younger. These died directly from the effects of the disease, one after a relapse, and the other early in its onset. The symptoms did not vary from those already noted in the cases treated, the most marked being depression of the nervous system and general prostration—not usual in the early stages of other diseases.

Cases of whooping-cough during the epidemic of that disease, which has lasted now nearly one year, have been very amenable to treatment, no death having occurred in any cases treated from the beginning of the disease. But since the beginning of the epidemic of catarrhal fever, cases complicating that disease have proved much less amenable to the influences of the remedies used, and two deaths have occurred from such complications. One case, a boy one year of age, affected with bronchitis, had nearly recovered, and was able to be out with his nurse, when he was suddenly seized with the catarrh and died within twenty-four hours. The symptoms were similar to those of capillary bronchitis.

I have not attempted to go into any exhaustive analysis of these cases. Some of them I was not able to verify with the clinical thermometer, and in none of them had I the opportunity to study the varying symptoms and temperature during the whole of the twenty-four hours, as may be done in a hospital practice; and yet I have been able to observe enough to convince me that when we have to deal with an epidemic of catarrhal fever, we have to do with a serious malady, either as a primary or a complicating disease. This disease is, according to my experience, much more serious than that of whooping-cough, and less amenable to treatment. The results are liable to be serious, whatever age is affected; but the young, the aged, pregnant women, and those reduced by other diseases, are peculiarly liable to suffer.

My principal object in this brief paper has been to call the attention of the profession to the deleterious influence of this disease upon pregnant women, and to what I deem to be the cause of such serious results.

As to the treatment, I have nothing new to offer. Tonics, particularly the preparations of cinchona, are perhaps as satisfactory as any—as far as constitutional treatment is concerned. Heart tonics are no doubt sometimes indicated. Children often get marked relief from the application of camphorated oil to the throat and chest, and a syrup containing some slightly relaxing agent, as syrup of ipecac or squill, combined with a little camphorated tincture of opium, to lessen the frequency and hoarseness of the cough, and in some degree allay the nervous irritation.

There certainly are few, if any, diseases which occur so frequently as epidemic catarrhal fever, and which so suddenly appear over widely-extended territories.

In view of the seriousness of the results frequently attending these epidemics, it well becomes us to study them in all their bearings. No doubt some of the many pages of medical literature devoted to diseases which a busy practitioner might not see once in a lifetime, might profitably be given to the discussion of this most common ailment.

HISTORICAL NOTE ON PROGRESSIVE PERNICIOUS OR IDIOPATHIC ANÆMIA.

By J. H. MUSSER, M.D.,
CHIEF OF THE MEDICAL DISPENSARY OF THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

In the historical introduction to his article on "Pernicious Anæmia," Immerman[1] gives to Biermer[2] the credit of having firmly established it as an independent affection, and devised a general term for the group of symptoms which go to make up the *ensemble* of that disease. Truly he says, "such cases (as B.'s) had been noticed and described before," and he refers, among others, to a series published by Zenker[3] in 1856. Further, he says, that "Gusserow was really the first to enrich gynæcological literature with an account of several cases of 'extreme anæmia in pregnant women.'" It is my purpose to show that, long before either of these men wrote, the disease in both its forms, in connection with or independent of pregnancy, was not only fully recognized but graphically described by one of our own countrymen.

That Biermer was not the first in the field, is not a difficult task to prove, for Prof. Pepper,[4] in a very interesting article, shows that Marshall Hall was acquainted with the disease, and that Addison admirably described it in his work on "Diseases of the Supra-renal Capsules," published in 1855. Dr. Fred. Taylor,[5] writing on the history of the affection, considered that Addison should "be recognized as the first known observer of fatal anæmia," while, since his time, the disease has never been "lost sight of at Guy's." The earliest publication that Taylor refers to is an abstract of one of Addison's cases in the *Medical Gazette* of March, 1849. He then gives abstracts of sixteen undoubted examples collected from *Guy's Hospital Reports and Records*, as well as from the *London Path. Soc. Trans.* All of which had been published prior to Biermer's article. Drs. Wilks, Moxon, and Habershon were especially well acquainted with the disease, labelling it Idiopathic Anæmia. Earlier yet, in 1823, Andral probably recognized it.

We have had occasion lately to go over the literature of anæmia, and, of the numerous works, to consult Williams' "Principles of Medicine." In the chapter on that subject, he refers to a series of cases of anæmia, generally fatal and connected with pregnancy, published by Dr. Channing, of Massachusetts. The article referred to is printed in the *New England Quarterly Journal of Medicine and Surgery*, No. 2, October, 1842, entitled "Notes on Anhæmia, principally in its connection with the Puerperal State, and with Functional Diseases of the Uterus; with Cases." By W. Channing, M.D.

The paper is divided into two parts; in the first part the cases are given, in the second part remarks are made on them. The first part is sub-divided: 1. Cases of anæmia without any connection with pregnancy. 2. Cases connected with pregnancy. In the first part seven cases are detailed, but no dates are given as to the time any of the patients were under observation; in the second portion of his clinical report, one of the cases (Case XII.) came under his observation as early as 1832. It will thus be seen that Channing took notes of the disease before any were ever published on it, and it is probable that as early, if not earlier, than any other observer, he distinctly recognized it. It was not familiar to Channing alone, but others noted it. Thus Dr. Spear had seen four fatal cases; Stevenson, Jackson, and others report cases. It was therefore a clearly defined disease in the minds of the physicians about Boston, as early as 1832-'35, and although it may have been known to Addison at that time, we have no proof of it, as the first public record of his case was in 1849.

As the journal from which these notes were culled is in the hands of but a few, and as pernicious anæmia is exciting so much attention, I will make an abstract report of Channing's cases, with an analysis of them, and an abstract of his remarks. Then, too, his observation is so truthful, it is but just that his good work should be revived.

The first series of cases—seven—do not demand much consideration, as they were not in all probability cases of what now is termed pernicious anæmia. In all save one, there was a definite cause for the anæmia, while but two of them died.

CASE I.—Was that of a young man, dying of anæmia without organic disease, nor was there any lesion found at the autopsy.

CASE II.—Female, single; disease followed repeated bloodletting; she was not emaciated at the time of death. Autopsy: nothing morbid; heart natural.

CASE III.—Female; married; not pregnant; disease followed menorrhagia; "*rarely known flesh so well preserved midst symptoms so grave;*" complete loss of strength; recovery.

CASE IV.—Anæmia following a pneumonia which occurred three months after confinement; pallor, loss of strength; no emaciation; recovery.

CASES V, VI, VII.—Are similar in that they originated from uterine hemorrhage and are of interest because of some special symptoms common to the three, as the blanched appearance, *profound prostration*, absence of emaciation, and a *sense of beating in the head.* Channing especially notes the appearance of the superficial veins. They are, *as is almost always the case, most visible on the inside of the wrist; they present the appearance of bright pink or rose-colored lines just beneath the skin; some of them seem flat.* As before mentioned, it can not be said any of the above list were cases of idiopathic anæmia, yet in all probability, with the modern means of diagnosis, some would have been thus classified.

Channing remarks, "I might add easily to these cases; but they will suffice to show how strong the anæmic tendency may become from excessive uterine action alone, though connected with a periodical function, and how comparatively safe it (this tendency) is when regarded with the *true disease* which attends pregnancy or follows delivery."

[4] American Journal of the Medical Sciences, October, 1865.
[5] Guy's Hosp. Rep., vol. xxiii., 3d series, 1878, pp. 183–200.

He then narrates a different class of cases. "These," he says, "have connection with pregnancy, or the puerperal state. At least they occurred during one of these states, or having begun in the first, the disease has continued into the second. The disease in these connections has always been fatal." He says he knows of a well-marked case *that was cured.*

Cases VIII, IX, X.—Cases of Dr. Spear, who had seen five cases. Bloodlessness extreme; animal functions not impaired; no emaciation; rapid pulse; very little suffering; death. No autopsy.

Case XI.—Mrs. W., confined three weeks previous to death; no milk, mammary abscess; no appetite, vomiting, diarrhœa; *tumultuous action of the heart;* mind clear; death. No autopsy.

Case XII.—Seen with Dr. Stevenson and Dr. Jackson; notes by Dr. S. Mrs. H., æt. 25, of robust appearance and uncommon bodily vigor; healthy pregnancy; delivered Dec. 15, 1832, of her third child; no hemorrhage. She died Jan. 3d succeeding, after an illness of sixteen days. I cull from the daily notes the following: Ol. ricini given December 17th. Next day severe diarrhœa. Diarrhœa soon checked; nausea and vomiting occured at intervals; appetite was good; thirst great. Pallor, increasing until death; surface like wax; extremities cold, at times numb; *flushes and chills;* warm moist skin; increase of temperature. Pulse from 120 to 140; at first quick and strong, then feeble and rapid; palpitation; pulsation in head, breast, and arms; sighing, faintness, syncopal attack, overpowering sense of faintness and fatigue; bodily efforts produce panting and distress. Headache, intolerance of light and sounds; slept considerably at first; pupils at first contracted, afterwards dilated; delirium slight towards evening by second day, and by sixth day *excitement of mind, which increased till evening, when she talked incessantly.* Cough throughout; respirations laborious towards end of illness. Urine at first scanty, afterward abundant (4 pts.); frequently passed; turbid and offensive, until four days before death; no albumen. Channing adds that she was not emaciated.

Autopsy.—Adipose membrane full of fat. Serous effusion in cavities of thorax. Heart pale and flabby; no blood flowed on division of its vessels. Spleen rather large. Channing adds to autopsy notes that the textures were dry and pale; blood small in quantity, pale, liquid, uncoagulated.

Case XIII.—Mrs. W., æt. 29. Three children, boys; health good while pregnant. Last labor March 5, 1836; normal; no hemorrhage; abundant milk, which began to diminish by end of second week, and disappeared in third. Mammary abscess second week, discharging the middle of the third week. "We now come to those symptoms which we may fairly call anæmic." Debility; chilliness; irritable state of whole system; pallor; clean, pale tongue; thirst; loss of appetite; constipation; inability to stand the mildest cathartic. Especially noted perpetual consciousness of *sounds in the head like sawing wood,* but auscultation revealed no murmur. Death seven weeks and three days from her confinement, or two days over four weeks from discharge of abscess.

Autopsy (J. B. S. Jackson).—Whitish coagula in long sinus, ecchymoses of internal surface of dura mater. Heart moderately firm, some quite soft light-colored coagula in both sides. Blood unusually pale.

Case XIV.—Mrs. W., æt. 42. Pregnant thirteen times; four miscarriages. Last labor in April. (Notes three weeks before death, October of same year.) Confinement natural, without much hemorrhage. Three days after began to fail. Pallor extreme; skin warm and dry; one or two chills. Pulse ranged about 120, small and irritable; susceptible to noise; irritable temper. Appetite poor, constipation, laxative over-act. In last week nausea. Lost some flesh.

Autopsy (Jackson).—Lungs œdematous. *Heart usual size, flaccid, pale; pallor greater than of voluntary musles, which were more so than usual.* Left ventricle thin; external pericardial surface somewhat red, inner surface stained with blood. *Blood watery, pale red; some flocculent putrilaginous-looking coagula in right side; moderate quantity of fibrin in right ventricle, and pulmonary artery of dull yellowish color and quite soft; some of same in left auricle. Contents of veins appeared morbid—blood mixed with a thick,* whitish opaque fluid like pus. Spleen large, dark *red, soft; on pressing on it a thick grumous fluid forced out in great abundance, leaving proper tissue colorless.*

Case XV.—Mrs. W., æt., 22, delivered lately of second child, never knew disease or trouble. Dr. C. saw her two weeks after confinement. No emaciation; face, lips, tongue, edges of eyelids and angles of eyes entirely white—not pearly white, but *there was the slight yellow mixed with the white which gave it a dirty hue.* Expression anxious; was feeble, with a hollow voice; appetite gone. Slight suffering, but soon took to bed from debility. Noises in the head, puffing or buzzing. No sleep. *One symptom very striking*—color of blood in the veins—bright pink, especially in veins of wrist; vessels flat, not round. *Purpura over extremities.* Pulse always rapid; respiration hurried. Death in three weeks. No autopsy.

Case XVI.—Mrs. K., anæmia began and was fatal during pregnancy. Had had several children still-born; out of health several years. Not well during this pregnancy. Seen April 2d, pallor, sore mouth, swelling and soreness of genitals. April 7, increase of all symptoms; roaring in ears; delirium; diarrhœa; death, April 11.

Case XVII.—Mrs. B., fourth child. Months before last confinement, pallor, ringing in ears, tendency to faintness, palpitation, aphthous mouth, diarrhœa, and vomiting. Delivered October 27, 1841; normal. Ol. ricini third day, followed by diarrhœa, at first not urgent; in a week, very extreme and continued till death. Pulse 120 to 144, very feeble.

Pernicious anæmia, as understood at the present day, in addition to the facts secured by means of the microscope and the ophthalmoscope, is characterized by gradual and increasing pallor, loss of

strength, absence of emaciation, fever of an irregular type; by languor to extreme prostration, giddiness, dulness or feebleness of intellect, somnolence, delirium, coma; by a rapid, feeble, irregular pulse, palpitation of the heart, feeble or absent impulse and first sound, cardiac, arterial, and venous hæmic murmurs; by hemorrhages; by breathlessness on exertion or excitement; by loss of appetite, weak digestion, perhaps nausea and vomiting, or a diarrhœa. It occurs at any age in either sex.; has no positively definite cause, runs its course in from six weeks to six months, and is generally fatal. After death, along with the changes in the blood, there is found fatty degeneration of the heart, the liver, and the kidneys.

Reviewing the last series with the light of the present, it will be seen how admirable is the description, and how wonderfully acute an observer Channing must have been. In the history of each case may be found one or more symptoms, considered at this time as essential; all of the symptoms are noted at one place or another. The record of Case XII. presents a perfect picture of the disease, while the following only pale in the light of it. The thirteenth case might, from the anatomical appearance of the spleen, be judged leucocythæmia, but the clininal notes portray anæmia. The twelfth case is worthy of note from its rapid progress.

In his general remarks Channing refers to the brilliant whiteness, dryness, smoothness and warmth of the skin as a constant symptom; to the absence of emaciation and the occurrence of great debility; to the fact, most characteristic, of death coming on without grave enough symptoms, "that the mysterious malady has not its place in any organ;" to the patient being indifferent, serene, even prophesying death calmly; to the noises in the head; the tumultuous action of the heart; the labored respiration, the nausea, diarrhœa, and uræmia. He speaks of hemorrhage, but does not appreciate its value as a symptom. He lays great stress—more than modern writers—on the appearance of the veins: they are scarce, flat, pink, increased on the wrists; not pathognomonic of fatal anæmia, as he notes this state in other anæmic cases. The pathology he admits is obscure, but thinks the disease has its seat in the small vessels; that the small vessels have much to do with the formation of blood (a shrewd guess), and that their function is subverted; this is true, for one reason, because of the absence of emaciation in the midst of the universal absence of all functions that sustain flesh. He calls attention to the connection of pregnancy to the disease, and claims to be the first to do so. The prognosis is almost always fatal; he knows of one recovery. Treatment is futile; transfusion, the *modern method*, he disapproves of, for it is filling empty vessels of an unlike fluid.

PHILADELPHIA, 3705 POWELTON AVENUE.

CHOREA IN THE NEGRO.

BY WHARTON SINKLER, M.D.,
OF PHILADELPHIA.

THE question of the frequency of chorea in the negro race has excited some interest since Dr. Weir Mitchell sent out his inquiry on the subject through the Smithsonian Institute several years ago. He states[1] that, in answer to his circular, many physicians in the Southern States of this country and in Cuba sent him replies. The almost universal testimony was that the disease was very rarely met with in the negro. Indeed, forty-nine of sixty physicians had never seen a case in the black, and the remainder considered it infrequent in that race. However, some physicians in Virginia wrote Dr. Mitchell that they regarded chorea as common in one race as the other. Dr. G. W. Benton. a physician of large practice in a portion of Florida thickly populated with negroes, told me a few days ago, that in thirty years' experience he had never seen a case of chorea in a black. On the other hand, Dr. S. H. Stout, of Chattanooga, Tennessee, to whom I am indebted for a long and interesting communication on the subject, believes that chorea is quite as common in blacks as in whites; indeed, his figures show that it is more common in the former. He states that he can recall twenty-one cases of chorea which have come under his observation. Of these, thirteen were black females, four white and three mulatto females, and one white male.

Dr. Mitchell states "that the weight of evidence is in favor of the opinion that the black is less liable to chorea than the white." My own experience leads me to the same conclusion. Out of three hundred and nineteen cases of chorea which have been treated at the Orthopædic Hospital and Infirmary for Nervous Diseases in this city, most of which I have seen personally, but one belonged to the negro race.[2] This child was so light a mulatto, probably an octoroon, that it would readily be taken for a white child, and both of its parents were of light complexion.

I have seen in private practice one case of chorea in a black. The following notes were taken when the patient was first seen:

Melinda D., æt. 19 years, born in Washington, D.C. Married. Both parents are dead. She is a negress with dark skin, short woolly hair, and features peculiar to the race. She says that her mother was a mulatto and her father light-colored. She was always delicate as a child, has always been subject to headaches, and been nervous. Six months ago she had an attack of acute rheumatism, and was confined to bed with it for some time. She has been well of it only three months. The menstrual function was established at 14 years of age, and has been regular until about three months ago, when she became pregnant. Since becoming *enceinte* she has not felt well. About four weeks ago, she was struck on the knuckles of the left hand with a stick, the blow caused considerable pain, and the knuckles are still swollen and tender to the touch; a week after this irregular movements began in the left hand and soon extended to the shoulder and

[1] Lectures on Nervous Diseases, p. 143.

[2] According to the *Bulletin of the National Board of Health*, the colored population of Philadelphia is 35,000, and the white population 851,339; or 1 to 24.32. From these figures it is not unreasonable to suppose, if chorea was as common in both races, there should have been a larger proportion of colored persons among the cases of chorea above referred to.

left leg. The movements have been growing worse.

Present Condition (September 24, 1881).—The patient drags the left leg in walking, and when she sits down it is constantly in motion. The left arm is flexed and extended incessantly, and the fingers twisted and turned in every way. The face twitches and she makes a clucking sound with the mouth, but the speech is not affected. Voluntary effort increases the movements excessively. When she attempts to grasp an object, the arm is thrown into frantic gyrations and it is almost impossible to seize the object. While at rest the movements continue, but less violently. There is no paralysis. Dynamometer, right hand, 80°; left hand, 60°. Patella reflex present in the usual degree. She sleeps poorly, being often wakened, she thinks, by the movements. There is no tenderness over the spine. Heart sounds normal. Appetite poor. Bowels regular.

The patient was ordered five drops of Fowler's solution, thrice daily, and was seen at the end of five days very much improved. She was not seen again, as she left for her home in Maryland, in a day or two.

In this case there were two conditions which predisposed to chorea, namely, the attack of acute rheumatism and the pregnancy, and the blow on the wrist may have acted as an exciting cause.

Dr. Skinner, of Glasgow, Delaware, has reported a case of chorea in a black.[1] The patient was a pure negro girl, aged eighteen years. She had had subacute rheumatism, which was followed by bobbing and shaking of the head, and then general chorea. She menstruated regularly. There was an apex murmur heard over the heart, and this persisted after the chorea was well.

This is the only case of the disease in the black I have met with in medical literature.

MEDICAL PROGRESS.

Resection of the Stomach.—Dr. F. W. Koehler reports the case of a woman, aged 65 years, in whom this operation was performed for carcinoma. An incision was made, commencing about two inches below the ensiform cartilage, and terminating about two inches below the umbilicus. After all bleeding points in the abdominal wall had been attended to, the peritoneum was incised, and the stomach partly drawn out of the abdominal cavity. The cancerous mass was found in the greater curvature of the stomach, and extended from near the pyloric end half-way to the cardiac end. On cutting through the wall of the stomach, the cavity of the organ was found occupied by an offensive material, seemingly a mixture of food and cancerous tissue. This was carefully sponged out and the dissection then completed. During the removal of the tumor, three arteries of considerable size, were cut. The blood from these vessels was, however, directed into the cavity of the stomach, and, in a very short time, ligatures were placed around them, and they gave no further trouble. Having completely excised the growth, the cut edges of the stomach were held in accurate apposition, and about forty sutures inserted, they being placed very close together. It should be stated that the sutures were of silk, which had been soaked in melted beeswax, to which some carbolic acid had been added. After all the sutures had been put in, the stomach was returned to its position in the abdomen, and, it being certain that all hemorrhage had been checked, and that the abdominal cavity was absolutely clean, the external wound was closed, and the patient placed in bed, with the foot of the bed somewhat elevated. The operation lasted nearly an hour, and towards the last the patient's pulse was very weak. Stimulants were administered in moderate quantity, and, for a while, the patient seemed to rally nicely—the pulse growing stronger, and she herself growing fretful, declaring her position in bed an uncomortable one, and the covering too heavy. These favorable symptoms were, however, of short duration, and, in spite of stimulants, she gradually grew weaker and weaker, and at 5.30 P.M. expired.—*Louisville Medical Herald*, September, 1882.

Silvester's Method in Drowning at Paris.—Dr. A. Voisin communicated to the Rochelle Congress (*Gaz. des Hôp.*, September 5) the satisfactory results which have attended the great efforts made for some years past by the Paris Municipality to improve the treatment of drowned persons in that capital—efforts which Dr. Voisin has been the chief instrument in carrying out. He now reports the results which have been obtained: 1. The almost absolute certainty of restoring life to persons who have remained under water, or "between two waters," for a period varying from a few seconds to five minutes—no one formerly having been saved after three minutes' submersion. 2. He has succeeded in restoring to life persons who have remained under water from five to twenty minutes. 3. These results have been obtained in individuals not merely in a state of syncope, but in an asphyxiated state, as shown by their violaceous face and lips, their open mouth, and flaccid masseters. 4. These results have been gained in consequence of the excellent arrangements made for the rigorous carrying out of Silvester's method; the effectual application of warmth to the whole surface of the body by calorific generators; the ready access to warm baths and cold douches; the keeping the patient quietly in bed for some hours after his restoration; the whole system being administered by a well-trained and disciplined staff, which is kept in constant readiness.—*Medical Times and Gazette*, September 16, 1882.

Abnormal Presentations in Three Successive Pregnancies.—Under this heading M. Bailly (*Archives de Tocologie*, May, 1882) records the histories of three successive deliveries in which there was prolapse of the cord each time, and the presentations were two breech and one footling. The latter presentation occurred notwithstanding very persistent efforts to maintain presentation of the head by means of a Pinard's bandage worn during the latter months of pregnancy. As there was no pelvic deformity, the author refers this repeated abnormality in presentation to irregular formation of the uterus, in consequence of which the lower part was more capacious than the upper, and thus would accommodate more readily the larger pole of the ovum formed by the breech and reflected limbs than the fundus would. No attempt is made, however, to prove this opinion by actual measurements of the uterus.—*Edinburgh Med. Journ.*, August, 1882.

Treatment of Typhoid Fever with Ergot.—At the meeting of the Académie de Médecine held September 5th, M. Hervieux read, in the name of Dr.

[1] Philadelphia Medical Times, July 31, 1875.

Duboué, of Pau, a note on the treatment of typhoid fever with ergot. Dr. Duboué had been employing this method of treatment for seven years, and has now had a sufficient number of cases to warrant reliable conclusions. He believes that ergot is the most efficacious remedy which we possess to combat all the forms of typhoid fever, even the gravest cases.—*L' Abeille Méd.*, September 11, 1882.

Duration of Pregnancy.—Dr. Helen Idelson (*Petersburgh med. Woch.*) found that, of 4,370 patients in Prof. Horwitz's obstetrical clinic, only 488 could furnish the requisite data for the determination of this question—viz., the exact date of the last day of the last menstruation, and the maturity of the fœtus. After showing the great differences which prevail in various animals, and the great differences between the maximum and minimum admitted by authors in woman, she states as the result of her own researches, that the average period was 278.8 days—viz., a minimum of 226 and a maximum of 328, or a difference of 102 days. She sums up the results of her investigations as follows: 1. The duration of pregnancy amounts to 278.8 days, or nearly forty weeks. 2. The sex of the infant influences the duration, this being longer in female infants. 3. The heavier the child, the longer is the duration.(?) 4. The duration is longer in multiparæ than in primiparæ. 5. The younger the woman, the longer is the duration. 6. The duration is longer in married than in unmarried women. 7. The first movements of the child are felt, on an average, on the 135th day, but later in primiparæ than in multiparæ.—*Dublin Journal of the Medical Sciences*, September, 1882.

Treatment of Ascarides Lumbricoides.—Dr. Guermonprez (*Bull. Gén. de Thérap.*, p. 89, 1882) sums up a long article on lumbricoides thus: 1. Wormseed (whose action is not to be confused with that of santonin) is by far the best medicament for killing as well as expelling round-worms. 2. Santonin does not kill the worms outright, it excites them to livelier movements, and these may reflexly stimulate the intestine so as to expel them; but they may also only exaggerate the evil if there is obstruction. 3. Santonin is, therefore, by no means always to be chosen. It does no harm if the worms are young and not numerous; if they are mature and many, it may be dangerous even in reasonable doses. 4. The purgatives usually given with vermifuges probably do more than the latter to cause expulsion of the worms; simple evacuants will often suffice. 5. Ordinary hygienic means directed to overcoming the lymphatic cachexia of the patient, or simple change of food and abode, may at times be enough to rid him of the worms without any medicine whatever. 6. Hence our treatment should not be the mere routine administration of santonin, but should be determined by the circumstances of the case. Change of air, and of diet, and of simple evacuation, are not to be forgotten.—*Practitioner*, September, 1882.

Extirpation of a Tumor of the Cranial Bones and Meninges.—Langenbeck (*Gaz. Méd. de Strassbourg*, No. 6, 1882,) reports the case of a woman, aged 60, in whom there had developed in 1868, on the frontal prominence, an ulcerating tumor, probably caused by repeated wounds with a comb. It was removed in 1874, in 1878, and again in 1879, trepanning being necessary at the last operation. The tumor again developed, and in February, 1881, had attained the size of the palm of the hand. It was again removed, a large fragment of the bone and dura mater being taken away at the same time, it having been found that the disease had penetrated to the pia mater; a small portion of the latter was cauterized with chloride of zinc. The operation was done without the spray; the wound was filled with a blood clot, and dressed after Lister's plan. The wound remained antiseptic.

Langenbeck recommends the use of the Esmarch bandage for the head. The head is wrapped with gauze, and then the constricting band is carried around the head from the occiput to the forehead.—*Journ. de Méd. de Paris*, September 2, 1882.

The Treatment of Hydrarthroses. — Prof. Volkmann (*Centralblatt f. Chirurgie*, August 19), in reference to a discussion upon this subject at the Paris Société de Chirurgie, observes that in chronic effusion into the joints, he has several hundred times performed puncture of the joints, and followed it up by washing out the cavity with a solution of carbolic acid of from three to five per cent., without having ever met with any accident, or even the least disturbance, after this manipulation. As a general rule, from ten to fifteen glass syringes full, capable of holding each 45 grammes, had to be alternately employed, and the fluid allowed to run away, before this was discharged in a clear condition, showing that the synovial fluid, which the added carbolic acid easily renders turbid, was entirely removed, and the joint thoroughly washed out. In order that the carbolic acid might exert its influence on every part of the surface of the capsule, the joint was then moderately filled by the injection of from one to three syringes full, and then submitted for a short time to movements of flexion and extension. A larger quantity of the solution than this was never left in the joints, and even the slightest symptoms of carbolic intoxication have never been observed. After the washing-out was finished, the limb was always surrounded by a Lister dressing, and kept immovably for some time on a splint. When the effusion has not been of too old a date, recovery has always followed a single puncture and washing-out, although, as a rule, firm bandaging is required for the prevention of relapse, for diminishing the thickening of the capsule, etc. In bad cases, in which there has been great extension of the capsule and ligaments, due to large and old hydrarthroses, the punctures and washing-out have to be repeated two, three, even four times, at intervals of several weeks, before the capsule contracts sufficiently. Iodine injections, which Prof. Volkmann formerly employed frequently, he has now discontinued, as possessing no advantage, and occasionally giving rise to suppuration of the joint. In the worst cases, with great distention and thickening of the capsule, great villous formation, large fibrinous coagula, dropsy, riziform bodies, or *gonitis fibrinosa*, without fluid exudation, Prof. Volkmann always makes a double incision into the joint, and introduces two very short (sufficiently long, however, to completely enter the joint) drainage-tubes, which, after carefully washing out the joint, are left in as long as any secretions issue through them. He is unable to say how often he has performed this operation, which has been by far the most frequently executed on the knee, but certainly more than a hundred times. Even in these cases only disturbances of a very slight nature were sometimes met with, although the procedure was employed in bad cases of disease of the joints when great dropsical effusion was present. The general conclusion, therefore, is that both puncturing and washing-out the joint, and the double incision and drainage, with the aid of antiseptics, may be declared to be operations unattended with danger and followed by satisfactory results. How thoroughly Prof. Volkmann has been convinced of this may be inferred from the fact that for a series of years he allowed Prof. Rancke to attach a manometer to the trocar, in order to institute experiments on the intra-articular pressure in the living man. None of these experiments did the

slightest harm to the persons on whom they were performed; and it is to be much regretted that, owing to its having appeared only in the form of a Latin *Habilitationschrift*, this distinguished work of Rancke, in which he arrives at the most important conclusions concerning the conditions of pressure in the knee-joint and their variations in the various positions of the limb, are so much less known than they deserve to be.—*Medical Times and Gazette*, September 16, 1882.

New Method of Reduction in Dislocations of the Humerus.—Mr. Jas. E. Kelly recommends the following as successful when other plans have failed. The patient should be placed as close as possible to the edge of the couch, on his back, with his head low. The operator places the injured arm at right angles to the body, and standing against it, with his side to the patient and his hip pressed firmly, but not roughly, into the axilla, he folds the arm and hand of the patient closely round his pelvis, and fixes the hand firmly by pressing it against the crest of his ilium. The second stage, during which the reduction is effected, is very simple, consisting merely of a rotation, or version, of the surgeon's body with a force and rapidity which necessarily vary with the peculiarity of the dislocation —some yielding most readily to a sudden and powerful effort, and others to gentle and gradually increasing traction.—*Dublin Journal of the Medical Sciences*, September, 1882.

Obstruction of the Bile-duct: Formation of a Fistulous Communication between the Gall-bladder and Intestines: Cure.—Winiwarter (*Prager med. Woch.*, No. 21, 1882) reports the case of a man, 34 years old, in whom an indolent tumor formed in the hepatic region after what was supposed to have been an attack of perityphlitis; at the same time the fecal matter became clay-colored. The tumor increased rapidly in size; its puncture allowed the escape of two litres of a fluid precisely similar in composition to the bile, and the tumor was reduced in size about one-half.

Three weeks later, the tumor occupied all the right half of the abdominal cavity. The patient was slightly jaundiced, and although he retained a fair appetite, he progressively lost flesh. A diagnosis was made of dilatation of the gall-bladder, caused by obstruction of the bile-duct. The tumor was punctured a second time and four litres of bile withdrawn; in the next fortnight it was necessary to tap the tumor three times again. Finally, Winiwarter determined to establish a fistulous communication between the gall-bladder and the intestines. After having opened the abdominal cavity, he found the gall-bladder with its anterior surface adherent to the peritoneum and to the transverse mesocolon. After puncturing it, he fixed it by sutures to the ascending colon, and this portion of the intestine was fixed to the abdominal walls. Four days later the gall-bladder was emptied by means of a medium-sized trocar and canula, passed through the common wall of the intestine and gall-bladder and the canula left in place. The desired end was not however attained, as the feces remained discolored.

Five months later, the gall-bladder being reduced in size, a second attempt was made; on this occasion the bladder was surrounded by a loop of small intestine, to which it was fastened by sutures, a bistoury passed through the adherent portion, and a drain inserted. A small quantity of bile passed into the intestine, but the greater part escaped through the abdominal opening. The drain was left in place for eight days. At the end of three weeks, the attempt to close the abdominal fistula led to an accidental opening of the large intestine, by which an artificial anus was formed. The health of the patient nevertheless steadily improved, the external fistula became gradually obliterated, and the patient was cured.—*Gaz. Méd. de Paris*, Sept. 9, 1882.

The Treatment of Typhoid.—At the present time the treatment of typhoid fever is an opportune subject to engage the attention of the medical societies of Paris since the French metropolis is threatened with an epidemic of most serious proportions. The subject was brought before a recent meeting of the Académie de Médecine by M. Vulpian, who is applying his experimental skill to the service of practical medicine, and has been recently endeavoring to determine the value of the antizymotic treatment of the disease. The question is one of extreme importance, for it must be admitted that hitherto the advance of bacterial pathology has not resulted in that increase in our power over developed disease which might reasonably have been anticipated from so considerable an addition to our knowledge of the nature of morbid processes. There is strong reason to regard typhoid fever as of parasitic origin, and from this naturally follows an expectation that good may be done by germicide remedies which may reach the intestine without losing their influence. Nevertheless this method of treating typhoid fever has hitherto found little favor at the hands of practical physicians. Proceeding upon these lines, M. Vulpian has tried in turn iodoform, which caused only disgust; salicylate of bismuth, which, although of a certain efficacy, seemed to favor the occurrence of certain complications, such as dyspnœa and nasal and intestinal hemorrhages; boracic acid, which turned out as useless as iodoform; and, lastly, salicylic acid, to which M. Vulpian wished to draw the special attention of the Academy. It may be remembered that this was largely tried, especially in Germany, several years ago, but generally relinquished as being either useless or positively injurious. M. Vulpian found that when it was given in small doses, as one, two, or three grammes in the twenty-four hours, the results were almost *nil*, but if a quarter of a gramme was given every half hour, so that the patient took in the day about six or seven grammes of the pure acid, he believed that there followed an amelioration in the course of the disease both marked and lasting. Some patients presented the accidents of salicylism-delirium, which quickly subsided when the drug was discontinued, or a little albuminuria, but these were exceptional. In most cases these doses were well borne, and the beneficial influence of the drug was shown in improvement of the general condition and of the mental state, and especially in a fall of temperature, which had a permanence not observed with other antipyretic remedies, such as carbolic acid. These results are in striking contrast to those obtained by other physicians who have tried salicylic acid in typhoid. M. Germain Sée, for instance, declared that he had never observed a true and lasting defervescence to be obtained by its use, but only a transient fall of temperature of a few tenths of a degree. It remains to be seen whether the results obtained by M. Vulpian are not due to the series of cases thus treated having been of a mild type. The difference in epidemic severity is a fertile source of fallacy regarding the treatment of typhoid. Experimental physiologists are often apt to draw hasty and untrustworthy conclusions on points in practical medicine.—*Lancet*, September 16, 1882.

Precocious Menstruation.—M. Prochawnick reports the case of little girl, who died at three years of age from acute bronchitis, in whom there had been a discharge of blood from the vagina regularly every four weeks from the time when she was only one year old. The autopsy showed a much higher degree of

development of the uterus than is usual in such a young child, while the ovaries resembled those of a female at puberty.—*Gaz. Hebdom.*, Sept. 2, 1882.

Results of Marriages with Idiots.—Dr. Berkhan, in the *Zeit. für Psych.*, makes some interesting observations as to the capabilities of microcephalic and other idiots to propagate their species. A semi-idiotic man has been married for some years to a healthy woman; there is no family. A healthy man, married to an idiotic wife, has had three children by her; two of them are idiots. These cases support Vogt's view—that while female idiots may bear children, the male are very frequently incapable of begetting them. Marriages are very rare between male half-cretins and healthy women, but are not uncommon between healthy men and semi-cretinous females who may happen to own a little property. The author has never seen the progeny of these marriages arrive at maturity; if not still-born, the children usually die during childhood.—*Dublin Journal of the Medical Sciences*, September, 1882.

Laparo-hysterotomy for Complete Prolapse of Uterus and Vagina.—A remarkable case of the above method of treatment is recorded in a recent number of the *Berliner klinische Wochenschrift*, by Dr. Kuhn, who was induced to practise it by the writings of Professor Müller, of Bern. The patient was a virgin, aged twenty-seven, whose life had been passed in indigent circumstances, and whose physical development had suffered in consequence. She did not menstruate until the age of twenty-one, and this function was scanty and irregular. To remedy this she put herself under the treatment of some quack, and shortly after menstruation had followed this person's treatment (the nature of which is not stated), the uterus and vagina became, within two days, completely prolapsed. The patient was then aged twenty-four, and from that time until she came to Dr. Kuhn, had been treated in various ways, every kind of pessary having been tried without success. When she came under his care she was anæmic and thin. The prolapsus formed a tumor as big as a man's fist. The vagina was completely inverted, and the prolapsed uterus contained in the sac so formed. The hymen formed a fold about a centimetre deep. The cellular tissue between the vagina and the bladder in front and the rectum behind was unusually loose, so that neither of these viscera were prolapsed. In January, 1881, the operations of anterior and posterior elytrorrhaphy and perineorrhaphy were performed, with the result that the patient was for a time relieved; but the artificially narrowed vaginal orifice became again gradually dilated, and in July of the same year the patient returned to the hospital. In August, therefore, with antiseptic precautions, the abdomen was opened. Both ovaries were first removed. Then an oval slice was cut off the fundus of the uterus, so as to give a kind of island of raw tissue surrounded by peritoneum. This raw surface was brought into contact with the abdominal wound, and the uterus then stitched into its new position, so that the peritoneum surrounding the raw surface on the uterus was united to that of the abdominal parietes. The patient recovered well from the operation—though not quickly, for she was about seven weeks in bed, owing to prolonged suppuration of the wound—and the uterus remained in its new position. Nevertheless, the patient was not free from discomfort, for she still suffered from prolapse of the vagina, on account of which a fresh anterior elytrorrhaphy and slight perineorrhaphy was performed. This succeeded, and at length the patient was well. Dr. Kuhn raises the question as to whether the removal of the ovaries was justifiable in this case. His reason for doing it was that the possible risks of pregnancy, with the uterus adherent to the abdominal wall, might be prevented. We must congratulate him, at least, on the docility of his patient; for we doubt whether in England many patients would be found to go through so much for the relief of so little. The case is interesting, also, because it shows how small a part the uterus itself plays in the phenomena of prolapsus. In this case the symptoms continued, although the uterus was immovably fixed to the anterior wall of the abdomen. —*Med. Times and Gaz.*, September 16, 1882.

Sudden Death in Diabetes.—Prof. Frerichs recently read a paper on this subject before the Berlin Medical Society, in which he classified the causes of sudden death in diabetes as due either to paralysis of the heart, syncope, or to gastric disorders, accompanied by pain in the head, delirium, coma, and dyspnœa. He describes a number of cases in which death occurred under these circumstances, the second group being capable of subdivision into a second, in which the one symptom of dyspnœa was absent. He believes that none of the various theories are tenable which attribute diabetic coma to, 1st, lesions of the brain, such as anæmia, hyperæmia, or œdema of the pia mater; 2d, hyperglycosuria; 3d, uræmia; or 4th, fatty embolism. He, however, holds that the presence of acetone in the blood will explain all the symptoms in such cases, and promises a communication on this subject at some future time.—*Journal de Médecine de Paris*, September 9, 1882.

Gastrotomy for Carcinoma; Death after Three Days, from Inanition.—Dr. E. Rochelt reports a case of stricture of the cardiac orifice of the stomach, occurring in a man, 70 years of age, in whom he performed gastrotomy; the operation succeeded in all its details, but the strength of the patient had been so reduced by prolonged abstention from food that death occurred from inanition, no peritonitis having been caused, on the third day.—*Wiener med. Presse*, August 27, 1882.

Cerebral Localization in the Sensory Region. —Theodor Petrina (*Zeit. f. Heilk.*, ii.) reports six cases of his own in which there was disturbance of sensation in the limbs which had lost their motor power, where also after death there was found only lesion of the cortex of comparatively old date, such that the influence of shock or pressure could be excluded, and the symptoms could be referred directly to the lesion. Where sensation was affected the lesions were limited to a rather narrow region. The lower part of Broca's convolution, the convolutions of the isle underlying this, the lower third of the anterior central convolution, the anterior upper surface of the first temporal convolution, the upper third of both central convolutions, and the superior parietal lobule, that is, all the convolutions in the psycho-motor zone around the fissure of Rolando.

The loss of sensation from lesion of these localities consisted in a more or less decided weakening of the sense of pressure, or of pricking, or of locality and temperature, or of several of these. The sense of taste, smell, and color was not affected. These "cortical" anæsthesias differ in this limitation of loss of sensation from those hemianæsthesias which follow a destruction of the posterior third of the posterior limb of the inner capsule (the *carrefour sensitif* of Charcot).

Cortical lesions of the occipital convolutions give rise to no sensory paralysis. He concludes that the most anterior portions of the frontal convolutions and the surface of the entire occipital lobe are not the seat of sensory centres.—*Boston Med. and Surg. Journ.*, September 14, 1882.

Linear Rectotomy.—At the meeting of the Société de Chirurgie, held July 5th, M. Trélat communicated the notes of a case in which he had performed linear rectotomy for the relief of cancerous stricture of the rectum, with the most satisfactory results. The patient was a man, aged 56, and suffered from an epithelioma of the rectum, which originated outside of the anus, and extended beyond the reach of the finger in the interior of the bowel; he suffered from intense tenesmus, which prevented sleep, and wasting diarrhœa, and was in a greatly reduced condition. Without any very sanguine hopes of success, M. Trélat performed linear rectotomy with the galvano-cautery, in the manner proposed by M. Verneuil, the incision starting at the tip of the coccyx, and deeply dividing the rectum as far as the anus. The result of this simple operation was very satisfactory: the tenesmus ceased immediately, and his general condition improved in every way. His death, which before the operation was imminent, was postponed for seven months and a half.—*Journ. de Méd. de Paris*, August 26, 1882.

Cow-koumiss in the Diarrhœa of Infants.—Dr. Senitschenko, of Kasan, reports (*Petersb. Med. Woch.*, Sept. 2) that he has derived great benefit from the use of koumiss prepared daily from the milk of the cow. The infants were from three weeks to one year and nine months old, and suffered from dyspepsia, diarrhœa, or cholera infantum. He began with a teaspoonful every quarter of an hour, and after six hours increased this to a tablespoonful. The children soon became accustomed to it, and under its use the stools soon improved, and the frequent vomiting ceased. The children who were the subjects of rickets ceased to suffer from such constant thirst, while sleep became better.—*Med. Times and Gaz.*, Sept. 16, 1882.

Ether-inhalations in Angina Faucium.—Prof. Concata, of Bologna (*Rivista clin. di Bologna*, No. 3, 1882), has, for the last year or so, been accustomed to administer ether-spray as an inhalation in sore-throat. His method is simple. The patient takes the exit-tube of a Richardson's spray-producer in his mouth; sulphuric ether is sprayed against the pharynx for three minutes, and the treatment is repeated every three hours. Six cases so treated were cured without other means. The cases are all described as "anginas," of what variety is not quite clear. Each case, however, began with a rigor and a sharp attack of fever, with a temperature of 40° C. (104° F.). Swelling of the sub-maxillary glands in nearly all the cases, and pain and difficulty of swallowing in all of them, were noted. The tonsils were always swollen and protruding. One of the patients, a girl of 11, had scarlatina succeeding to the angina. Another patient, whose attack of sore-throat lasted eleven days, and was very severe, had enlarged spleen. Four or five days was the average duration of the attack; one patient, attended by Prof. Concato at home, got well in twelve hours. It is set down as an advantage of the ether treatment that it very speedily puts an end to the local pain and diminishes the swelling, and so quickly restores the power of easy swallowing. In some cases the fever quickly subsided at the same time. The treatment is worthy of further trial.—*Practitioner*, September, 1882.

Suture and Resection of the Intestine.—M. Madelung has recently published a monograph on this subject (*Arch. f. klin. Chirurg.*, xxvii.), in which he analyzes the causes which have lead to success or failure in the cases which have been reported. In the majority of cases he believes that failure has been due to insufficient or improper technical details. He believes, basing his conclusions on experimental data, that the method of *invagination* should be absolutely rejected, even though it has been successful in two cases, one of which was his own: his reason for this opinion, is that the extended separation of the intestine from its mesentery necessarily causes gangrene of that portion of the bowel. He advocates the method of double suture as employed by Czerny. The author advises, at the time of operation, when the diseased intestine has been drawn outside of the abdominal cavity, to close the wound in the abdominal walls by one or two deep temporary sutures. The needles should be extremely fine, round, and curved, as recommended by Larrey, and fine silk should be used for the sutures. The points of suture of the intestine should not be more than three millimetres apart, as it should be remembered that the subsequent meteorism will probably double this distance. To avoid retraction of the intestine, the incision should divide its walls obliquely and not circularly. Madelung proposes the replacing of the metal disks, employed in Bozeman's and Czerny's method, by little disks of calves' cartilage.—*Gazette Hebdom.*, September 15, 1882.

The Urine in Infectious Diseases.—A series of researches, chiefly by Selmi, Brouardel, Boutmy, and Gauthier, have shown that peculiar alkaloids, to which the term "ptomaines" has been given, develop in dead animal tissues which are in process of putrefaction. They present similar chemical reactions to the alkaloids which are found in poisonous fungi. Bouchard, according to the *Revue Médicale*, has suggested that, since the ptomaines only appear in tissues which are charged with microscopic fungi, it is permissible to suppose that the cadaveric alkaloids are merely the products of the "disassimilation" of vegetable organisms. Further, if bacteria living in the dead animal tissues produce bacteria, it is possible that the same bacteria, growing in a living organism, may produce substances analogous to ptomaines. Bacteria seem to appear in the living body in all infectious diseases. Hence M. Bouchard has endeavored to ascertain whether, during the course of infectious diseases in the human subject, any trace of these alkaloids can be found in the urine. His observations were made on cases of typhoid fever, "infectious pneumonia," and "infectious pleurisy," whatever the latter disease may be. All were dieted and no medicines containing alkaloids were given to them; and the urine was carefully preserved from putrefaction. An analysis showed that they contained alkaloids having all the characters of ptomaines. A series of normal urines examined, and specimens from patients suffering from pulmonary emphysema, valvular disease of the heart, presented no trace of alkaloids. The conclusion, however, is not beyond question, since M. Pouchet has affirmed that the presence of alkaloids may be constantly demonstrated in normal urine.—*Lancet*, Sept. 16, 1882.

Preventive Treatment of Abscess of the Breast.—Prof. Le Fort attributes the ordinary occurrence of mammary abscess in the superior outer portion of the breast to the pendant position of this portion of the gland. To avoid, therefore, the occurrence of mammary abscess, he advises that the breasts should be drawn to the median line and fixed there by a body bandage. By this means the breasts are prevented from hanging down at the sides, and the dragging due to their weight is avoided.—*Journal de Médecine de Paris*, September 9, 1882.

Morphiomania.—In a paper read at the Rochelle meeting (*Gaz. Hebd.*, September 2), Dr. Landowsky drew attention to the fact that besides the cerebral disturbances caused by the excessive use of morphia,

venous congestions were also induced by it, which in the long run led to permanent lesions, especially of the kidneys, inducing albuminuria or glycosuria. He also called attention to the too great frequency with which injections of this powerful agent are entrusted to inexperienced nurses and the patients themselves.—Prof. Verneuil remarked upon the frequency with which patients who come to consult surgeons have before that time been trying and abusing the hypodermic method. In their case a condition is generated, which at the time they may have to undergo an operation may compromise their existence by their intolerance of chloroform, or later on expose them to the occurrence of fatal erysipelas or diffuse phlegmon—not that they are still under the influence of morphia, but have become through it the subjects of glycosuria, albuminuria, etc. —M. Rochard, in relation to the colossal doses that are sometimes employed, cited the case of a lady who injected as much as three grammes (forty-five grains) of the hydrochlorate of morphia daily. He further remarked that even when large doses are injected, neither constipation, loss of appetite, nor any other affection of the digestive organs is produced, while even small doses taken into the stomach produce these effects.—Dr. Landowsky has observed in several women, who accustomed themselves to excessive injections, that small mucous bursæ formed on the sides of the first phalanx of the index and median finger, which are due to the manner in which these morphiomaniacs practise the injection rapidly with one hand when they are alone. In doubtful cases, the existence of these bursæ may throw light on the diagnosis.—*Med. Times and Gaz.*, September 16, 1882.

SYPHILIS AND ALCOHOL.—In a recent memoir published in *La France Médicale*, M. BARTHÉLEMY calls attention to the exceptional gravity of syphilitic skin eruptions in patients addicted to the habitual use or abuse of intoxicating liquors. The observations which he gives were all collected while the author was chef de clinique in Fournier's service, and relate exclusively to the waiter girls employed in "brasseries," who receive the name of "inviteuses," because it is their business to have as much liquor ordered as possible. In the pursuit of this métier, they are obliged to drink large quantities of intoxicating liquors; one of them absorbed in one day forty-two glasses of beer, five liqueurs, and one "grog Americain;" this, of course, was an exceptional case; but most are continually drinking, in order to incite customers to order for them. When these girls contract syphilis, every symptom, even the primary chancre, is of gravity. In one case the eruption did not disappear from the cutaneous and mucous surfaces for ten years. The chancre in one case spread and became as large as a silver dollar, and was surrounded with an extremely indurated border, and notwithstanding treatment, the chancre lasted three months. In another case (Obs. III) the chancres were still present when a generalized papulo-hypertrophic eruption appeared over the whole body.

It was remarked also that secondary and tertiary eruptions appeared much more rapidly, were of greater intensity, and of longer duration.—*Med. and Surg. Reporter*, September 2, 1882.

HYGIENE OF THE ELECTRIC LIGHT.—DR. SIEMENS, in his able address at the British Association, justly lays stress on the hygienic advantages of the electric light. He considers that the principal argument in its favor is furnished by its immunity from products of combustion, which not only heat the lighted apartments, but substitute carbonic acid and deleterious sulphur compounds for the oxygen upon which respiration depends. The electric light is white instead of yellow, and thus enables us to see pictures, furniture, and flowers as by daylight; it supports growing plants instead of poisoning them; and by its means we can carry on photography and many other industries at night as well as during the day. The objection frequently urged against the electric light, that it depends upon the continuous motion of steam or gas engines, which are liable to accidental stoppage, has been removed by the introduction into practical use of the secondary battery. This, although not embodying a new conception, has lately been greatly improved in power and constancy by Planté, Faure, Volckmar, Sellon, and others, and promises to accomplish for electricity what the gas-holder has done for the supply of gas and the accumulator for hydraulic transmission of power. It can no longer be a matter of reasonable doubt that electric lighting will take its place as a public illuminant, and that, even though its cost should be found greater than that of gas, it will be preferred for the lighting of drawing-rooms and dining-rooms, theatres and concert-rooms, museums, churches, warehouses, show-rooms, printing establishments, and factories, and also the cabins and engine-rooms of passenger steamers. The extreme brightness of the luminous parts is, however, dazzling and unpleasant.—*British Medical Journal*, September 2, 1882.

ATTENUATION OF VIRUS.—At the International Congress of Hygiene, recently held in Geneva, M. PASTEUR read a paper on this the most valuable outcome of his remarkable researches on chicken cholera. He showed that a virus, even when depending upon an organism, can, without any marked change in its general morphology, be so attenuated in its virulence as to produce germs in culture fluids which are capable of communicating only a transient malady robbed of the fatal dangers attending the access of the virus in its natural state.

This modification, or attenuation, of the virus is produced by its simple exposure to the oxygen of the air, and can be produced not only in the case of the virus of chicken cholera, but also in the case of splenic fever, and it is probable that future studies will still further extend the list of maladies which can be thus deprived of their dangers. M. Pasteur's communication is, however, mainly concerned with the application of this principle of attenuation to a new virus—that of hydrophobia. On the 10th of December, 1880, a patient, after having been bitten by a mad dog, died of hydrophobia in the Sainte Eugénie Hospital in Paris. Two rabbits inoculated with the buccal mucus of this case promptly died, and M. Pasteur was able to recognize the presence of a specific organism in their blood. This organism was capable of cultivation and, when inoculated in the blood of other rabbits, proved rapidly fatal. It was then found that while this poison was not harmful to adult guinea-pigs, it soon destroyed these animals when they were only a few days old, the virus at the same time greatly increasing in virulence as regards guinea-pigs, while it nearly lost its poisonous property for rabbits. Oxygen, also, in the case of this salivary virus, as in the virus of chicken cholera, is capable of producing attenuation of virulence, and rabbits inoculated with this harmless virus are able to resist the action of virus in which the original virulence has been retained.

The value of this method of attenuation of virus so as to produce a protective vaccine is even more firmly established by the discovery by Pasteur of still a fourth virus, that of the typhoid fever of the horse, which also can be rendered harmless.

It would seem, therefore, that in this method of attenuation we may hope to find a means of preventing disease as valuable as the discovery by Jenner, of the protective power of vaccinia.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, OCTOBER 7, 1882.

CONCUSSIONS OF THE SOLAR PLEXUS.

THERE are so many varied consequences that may follow an injury or contusion of the abdomen, the enclosed viscera are, comparatively speaking, so poorly protected, their serous covering is so extensive, their nervous and vascular supply so large, that such accidents are among the gravest which fall under the notice of the physician or surgeon. In the vast majority of cases, however, they produce their dangerous or fatal results in some well-understood manner; a rupture of the peritoneum or of the intestine, of the stomach, liver, or kidney; extravasation of blood into the peritoneal cavity; peritonitis and speedy death, summarizing perhaps the usual course of the graver class of cases. In milder instances, rupture of muscle, effusion of blood into the abdominal parietes, followed by hernia, by abscess or by sloughing, constitute a not infrequent series of symptoms. Or again, as in two cases reported in a recent issue of THE NEWS, a circumscribed peritonitis may occur and run a favorable course, terminating in recovery.

None of these, however, have the medico-legal interest and importance which belong to those cases in which death follows immediately upon the receipt of an abdominal injury, and yet in which careful post-mortem examination fails to reveal the slightest evidence of traumatic or other changes. There is certainly a wide-spread belief, both within and without the profession, that death does result from such blows, through their effect in some mysterious way upon the solar plexus and its numerous branches, and yet we are compelled to admit, after a careful survey of the literature of the subject, that no well-authenticated instance of the kind has yet been recorded, unless we except the one reported in our present number by Dr. Beach. Those contained in the various works on Medical Jurisprudence are, without exception, either so carelessly reported or devoid of pathological detail as to fail to carry conviction, or else, as in the cases of Mr. Wood, quoted by most of these authorities, there were lesions discovered sufficient in themselves to produce death.

It could not, of course, be denied, that in an individual with a weak heart, with fatty walls, or with insufficient valves; with atheroma of the cerebral bloodvessels; or with advanced structural changes in any important viscera, an abdominal contusion, with the sudden gasping for breath, the rapidly increased vascular tension produced by it, and the subsequent condition of exhaustion might precipitate a fatal result which would otherwise have been delayed. In such cases, however, an autopsy would disclose the underlying pathological condition. In the absence of any such antecedent disease, and of any evidence of structural injury from the blow itself, it is a very serious matter to pronounce upon the cause of death, especially when, as in the case in question, the life or liberty of a fellow-being depends upon the medical opinion.

While it may be conceded that, in a certain number of instances, no other explanation appears to offer, it must at the same time be remembered that our methods of investigating pathological processes are not yet so exact as to detect with certainty all possible causes of death, and that it is our professional duty, above all in medico-legal cases, to state with positiveness only that about which there can be no reasonable doubt.

We can however say that the most probable explanation as to the mode of production of sudden death in these cases of blows on the epigastrium, as well as when caused by the drinking of large amounts of cold water, is to be found in the classical experiment with which the name of Goltz is connected (klopfversuch). It is found that when the pleuro-peritoneal cavity of a frog is opened and the surface of the intestine smartly tapped, after a few moments the heart is arrested in diastole. If, however, the mesenteric nerves, the ganglionic cords on each side of the aorta, the spinal cord below the medulla, or the vagi nerves are divided, no such effect is produced, thus proving that the arrest of the heart is due to reflex stimulation of the cardio-inhibitory centres in the medulla, the afferent fibres passing through the mesenteric nerves and sympathetic while the efferent impulses pass through the pneumogastric. Bernstein has also shown that the same effect will follow electric stimulation of these nerves.

Though the same general conditions hold in mammals, its demonstration is a matter of much greater difficulty. Asp has, however, been able to produce reduction in the rate of pulsation by stimulation of the central end of the splanchnic nerves; from analogy, therefore, the same *modus operandi* may with safety be concluded to hold.

The nerves of the abdominal cavity are not the sole paths through which the reflex inhibition of the heart may be produced. Thus in rabbits, the heart is arrested in diastole when the animal is caused to inhale the vapor of ammonia, the efferent path in this case lying in the fifth pair of nerves; and it is probable also that the sudden arrest of the heart in chloroform inhalation may be produced in the same manner; while in the frog, crushing the foot with a blow is often capable to stopping the heart.

In ourselves, fainting from pain is doubtless produced in the same manner, through reflex inhibition of the heart.

As regards the dangerous effects produced by the drinking of ice water in large amounts, when in a condition of exhaustion, we recall one instance where loss of consciousness and extreme slowing of the heart were produced by the ingestion of ice water during a long swimming match; and the trainer, who was ignorant of these physiological principles, was charged with poisoning his man.

DRUGGISTS AS VENEREAL SPECIALISTS.

THE various evils to the profession and to the community arising from the wide-spread practice of "counter-prescribing," have been repeatedly set forth in medical and lay writings, and are, indeed, so obvious that, as a rule, they require no explanation. There is one class of patients, however, who are pre-eminently the victims of this unlawful custom, and whose sufferings do not fall under the notice of the public, or even of the profession at large.

The young men among the poorer and middle classes who contract some form of venereal disease, constitute a very large percentage of the whole number, and among them there are few who do not, at least at first, apply to some apothecary for relief. The reasons for this are to be found in their limited means which often do not permit them to pay a physician; in their inability to spare the time from their work to attend at a dispensary service; and in their natural dislike to confide in the family doctor, or in their older and more experienced friends. Under these circumstances they seek a prescribing druggist—who is only too easily found—and ask for something which will cure their ailment. The routine practice, and we speak after a large experience with such cases, is that the patient names what he believes to be the disease with which he is affected, and that this is almost or quite all the information which is imparted to the druggist, who then proceeds to hand out the particular mixture which constitutes *his* remedy for that malady. As such patients are usually suffering for the first time, are ignorant of all technicalities, and often, unconsciously reverting to first principles, include under the generic term of "pox," all the varieties and complications of gonorrhœa, chancroid, and syphilis, it can readily be understood that no small amount of evil results from this procedure. A catalogue of the gross and altogether inexcusable blunders, which in hospital, dispensary, and private practice, have fallen under the notice of one or two physicans in this city during the past twelve months, would be quite sufficient to demonstrate the importance of the matter, and we are glad to learn that an effort is being made to obtain the evidence in such shape as to warrant its publication with names and addresses.

Apart from the unnecessary suffering to the individual, which moralists might assert to be a benefit in disguise, the harm and danger to the community are not to be disregarded. Such patients, unwarned and unenlightened, are but too often the accidental means of extending these diseases to innocent and equally uninformed people, and sometimes to whole families. It is impossible to estimate the injury which has thus needlessly been inflicted upon, first, the patients themselves; next, their immediate relatives or friends; and, finally, upon an undefined and extensive outside circle.

We are cognizant of cases where the most serious complications of gonorrhœa have been developed, and the patient's life imperilled by this form of malpractice; we know of one where syphilis was allowed to progress to the production of ulcerative lesions, followed by ineradicable deformity, while the patient was being treated with urethral injections; we have seen several—a large number—in which unrelieved phimosis and balanitis, treated with pastes and emulsions of copaiba, have gone on to partial destruction of the affected organ; one in which a specific iritis destroyed sight, and another, in which retention of urine from old stricture, almost killed the patient, no examination of any sort having been made in either instance, and the treatment in both being directed to lesions which did not exist. Such cases come under the notice of every one connected with a venereal dispensary or hospital ward, and in numbers which warrant our calling the attention of the profession to the subject. We are convinced that the only course which will result in an abolition of this outrageous form of swindling is one which aims at publicity, and we shall shortly have more to say in regard to the best means and methods of attaining this end.

DR. REITER'S REMEDY FOR INVETERATE PSORIASIS.

In that eccentric, but interesting periodical, Squibb's *Ephemeris*, we find a letter from Dr. Reiter, of Pittsburg, giving an account of a remedy for psoriasis, which he had used successfully *in propria persona*, and in many other cases. Any one having experience with inherited, or long-standing psoriasis, will admit the obstinacy with which it resists the action of remedies. Arsenic, at the present time, is the remedy most esteemed in its treatment. Dr. Reiter himself a sufferer to an aggravated extent, and inheriting his malady from several generations of sufferers, was finally cured by a tincture of burdock seed, recommended to him by an old farmer. The suggestion of the farmer was unconsciously based on the old therapeutical maxim—a remedy which has cured a case of disease, must also cure analogous cases. The precept proved to be sound in this instance, for the farmer's remedy having cured his own case was equally successful in Doctor Reiter's case. The official designation of burdock is *Lappa*, and it is borne on the secondary list of the pharmacopœia of 1870. The seeds are employed by Dr. Reiter in the form of a saturated tincture. Dr. Squibb in commenting on this preparation, suggests that a tincture be prepared in the proportion of two ounces of the crushed seeds to a pint of good whiskey, of which four fluiddrachms are given, well diluted, three times a day, after meals. Experience has shown that the remedy must be faithfully administered for a long time—for many months if necessary, in the more inveterate cases. The digestive functions, and the skin, are much improved by the remedy. The only constituents to which the curative results can be referred are an essential oil and a resin.

We find that burdock has long been used as a remedy in chronic skin affections, in strumous and rheumatic diseases. That it should have been kept on the U. S. Secondary List, is proof that its virtues are not highly esteemed. It has been relegated to domestic practice. If, however, it can be shown to cure cases of psoriasis of long standing, it deserves a more prominent place.

THE TREATMENT OF DIPHTHERIA BY LARGE DOSES OF CALOMEL.

There have always been advocates of this practice. In the letter of Dr. Reiter, communicating to Dr. Squibb his experience of the use of burdock, and published in the *Ephemeris*, we find the calomel treatment of diphtheria strongly supported. Since Dr. Squibb endorses Dr. Reiter as a practitioner of experience, and of good judgment, we must give his suggestions respectful consideration. Whilst we may profit by his practical therapeutical experience, we need not adopt his pathological views. Dr. Reiter says: "I have this winter verified my discovery perfectly. *Diphtheria is a functional disease of the liver.* . . Here you have the remote cause—*inspissated* blood. . . The proximate cause—*too much fibrine in the blood.*" The treatment —for the justification of which, we fear, the theory was invented—consists in the administration of calomel—one scruple the first dose, and then ten grains every hour until the symptoms improve, the fever subsides, the exudation stops spreading, and is detaching, etc. Says the old Doctor:

"Dear Squibb, smoke that in your meditative pipe—a boy of eight years with a half-ounce of calomel in his *prima viæ, not prostrated*, but *restored.* Trousseau is the only medical writer I know of who has not only seen, but has most accurately described all the protean forms of this most fatal malady—and not one of them escapes a clear and rational explanation by my etiology. I have read again and again his most graphic articles on diphtheria, and it pains me to observe how he staggers in trying to reduce his notions to a rational philosophy, lacking the light of a sound etiology."

Dr. Reiter argues in this circle: diphtheria is a disease in which the "power of destroying fibrine," ordinarily possessed by the liver, is lost, and hence the deposits in the throat. To cure such a disease, this function of the liver must be restored, and as calomel possesses this property, it must cure this disease. "Where a case has not reached a fatal condition," says Dr. Reiter, "from twenty-four to forty hours' medication effects a cure." We may not agree with the pathology; but what shall we do with the facts? If it be true that so large a proportion of the cases of diphtheria yield so soon to this treatment, we must admit that there is truth in the treatment, even if we deny the relevancy of the explanation. Further experience with a large number of unquestionable cases of diphtheria is necessary to establish in any, the exact value of the calomel treatment.

THE INDEX CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE.

We have just received the third volume of this extraordinary work. The whole medical world is debtor to Dr. Billings for his wise forethought and wide views. We have so often commended it and so often urged its support by liberal Congressional appropriations, that it is but iteration to express any opinion. Not only has no such work ever been attempted before, but probably none ever will be again, for a century at least, for this work is monumental and complete. It is indispensable for every medical writer and investigator.

The present volume consists of 1,020 pages quarto, with over 9,000 author titles and nearly 9,000 sub-

ject titles. It contains also over 4,000 titles of medical portraits, a feature in which this library excels all others, so far as we know. The volume extends from Cholecyanin to Dzondi.

The three volumes thus far published contain nearly 31,000 author titles, and over 129,000 subject titles. The mere enumeration of these figures prove the justice of the adjective we have used—monumental.

We regret that the appropriation is so small that the number of copies of Volume III. which it permitted to be printed is much less than that of the preceding volumes. We are informed, however, that the Government Printer has on hand a few extra copies which can be purchased at the nominal price of two dollars per volume. Persons who are so unfortunate as to be unable to procure copies would do well to apply for them to their representatives in Congress who would thus be informed of the extent of the demand for these volumes among their constituents in the profession, and be prepared to vote accordingly at the next session, when a bill will probably be introduced to publish an additional number of copies of this work for distribution by members of Congress.

We trust that the profession generally will use its influence in favor of a liberal appropriation for subsequent volumes.

It is proper at this time to call attention to another book, published in London—Dr. Neale's *Medical Digest*—which has a somewhat similar design to that of the Index Catalogue, but is constructed on a widely different plan. The second edition is just published and it will be a most useful companion to every writer and student. It is an octavo of over 700 pages with a very full and complete index. The Digest is not an index to all medical literature, or to a given set of journals, but a selected index as its name implies. It contains about 120,000 entries of articles, classified under proper headings, gathered from eleven of the leading British medical journals of the last forty years, and the *American Journal of the Medical Sciences*, as the representative of American medical journalism. Few men, writers, students, or simple practitioners, but will find in it a mine of wealth. Any one who will use it merely as a means of reading on his cases, whether for writing or for self-improvement will soon discover its great value.

WHOLESALE HUSBAND-POISONING.

Insurance companies, it is well known, as a rule will not insure wives for the benefit of their husbands, since wife-murder in various forms is so often resorted to, even in the absence of any such pecuniary stimulus. Not long since, however, we were startled by a despatch in our morning papers to the effect that over one hundred husbands in Hungary had been successfully, not to say happily, despatched by their enterprising wives. The Vienna correspondent of the *London Standard* (according to the *Tribune*) gives the details of this most remarkable of crimes.

In the little village of Melencze lived a certain old hag, Thekla Popov, who had reached the scriptural limit of three score and ten years, but who lacked the virtues pertaining either to her age or her sex. She figured as the "Married Woman's Best Friend," and justified her title to those who wished to complete the cycle of maid and wife by a speedy widowhood. She concocted her poisons and conducted her business so skilfully that for a long time no suspicion fell upon her in spite of the fact that her fame as a vendor of such elixirs must have been known to many a voluble woman, and the drugs must have been used again and again in most cases, lest a too sudden despatch of the unfortunate victims should betray her. Wronged maidens sometimes obtained her medicines, but wives, especially if young and comely, were her chief and most desired patrons. The cost, in view of the risk, was very moderate. Twenty-five to fifty dollars was the usual fee. On the average, husbands, even with an active market, only fetched thirty-five dollars. Her daughter, who was her only confederate, finally quarrelled with her and exposed her horrible practices, and the exhumation of the bodies of her victims confirmed the story. So far as we know, the practices of this Hungarian gypsy have been confined to her own village.

LESIONS OF THE ISLAND OF REIL.

In the subjects of aphasia, the lesions are not often limited to Broca's convolution, but also involve the island of Reil. The observations proving this have been made by Charcot, Meynert, Lépine, and others. The function of the insula has been lately studied by Dr. Perdrier, experimentally and clinically. He finds that destruction of the insula in animals does not affect motility or sensibility, but that it is a psychical centre, purely. In three examples in man of lesions of the insula absolutely limited to this area, there was hemiplegia, in which the arm was more decidedly affected than the leg. The paralysis of motion is complete, and there are no contractures or disorders of sensibility. The muscles of the trunk and of the face are not affected.

TREATMENT OF MENIERE'S DISEASE.

Dr. Nakachian has brought forward a number of new cases in illustration of the good effects of quinia in Ménière's disease, as originally shown by Charcot. The quinia is given in doses of 60 to 80

centigrammes (10 to 14 grains) per day for fifteen or twenty days. Then an interval of the same duration as the treatment is allowed, and the administration of the quinia is again resumed in the same way as at first. There are two or three or more of such periods of treatment, with the intervals of respite. During the administration of the remedy, the symptoms of the disease—the noises in the head and the vertigo—are increased; but during the interval a marked improvement is observed, each time greater. Recently Charcot has tried salicylate of sodium, and it is found to have the same effect as quinia. Probably other remedies producing tinnitus and vertigo will have some curative influence, the disturbance caused by the remedy supplanting that caused by the morbid process.

REVIEWS.

L'Instrument de Molière, traduction du Traité de Clysteribus de Regnier de Graaf (1668).
The Instrument of Molière, a translation of the Treatise on Clysters, by De Graaf. 8vo. pp. 127. Paris: Morgand & Fatout, 1878.

The French are a queer folk in many things. The syringe plays a not unimportant *rôle* in the family, literary, and dramatic life of our Gallic neighbors. No bride considers her *trousseau* complete without it; it figures largely in literature; and we remember to have seen on the stage of the Châtelet Theatre, in the "Sept Chateaux du Diable," one of the oddest scenes we ever witnessed. The gourmand, having over-eaten, called the doctor, who had barely closed the door, when there entered a procession of boys and men, beginning with a very small boy and ending with a very tall man, every one of whom, to the number of fifty or sixty, bore a syringe, likewise graded from the smallest size made to some big tin ones from eight or ten feet long. The terror of the patient, who fled in dismay before the agents of such decided medication and was followed in all his intricate doublings by his snake-like column of pursuers, was the source of unbounded merriment to the audience, in which women largely predominated. Louis XIV. gave more frequent audience to his Enema-Ministers than to his Ministers of State; the *Malade imaginaire* comforted himself after the fashion of the grand monarch, with clysters emollient, purgative, astringent, anodyne, detersive, carminative, refreshing, consolidating, or nourishing, according to necessity or whim. Molière so often introduced the instrument in his comedies that our translator ventures on a new caption to De Graaf's treatise, derived from the great satirist, and he describes the seventeenth century as "the age of clysters and of perruques."

De Graaf's treatise is at once instructive and amusing. With Plutarch, Pliny, and Galen, he traces the origin of the clyster to the Egyptian Ibis, which, when "incommoded by an excess of noxious humors, fills its bill with sea-water, introduces it into the intestine, which it sprinkles abundantly in order to start on its path the annoying burden." The polypharmacy which characterized the disgusting messes to be swallowed, was no less marked, though far less repulsive, in the enemata, many of them counting scores of various medicaments. For nourishing enemata, upon which he casts a rather doubtful eye, he commends wine, milk, bouillon, eggs, etc., which should be injected with sufficient force to pass the large and reach the small intestine, though he doubts the possibility of its passing in ordinary circumstances the ileo-cæcal valve, that "barrier of the apothecaries" or "pharmaceutical columns of Hercules," as were its amusing and significant titles in that "age of clysters." Some subtile portion of the clyster he thinks might traverse the pores of the bowel, enter the blood, give temporary vigor to the heart, but would give no veritable nourishment; and he instances Democritus who, at the age of 109, when death was under his roof, kept him at bay for three whole days by the mere odor of hot bread [toast?] so that he might survive the pending *fête* of Ceres, lest his sister could not make her proper devotions to the Goddess.

In one chapter, we find that the antiquity of the suppository is proved by an allusion to it as a usual remedy: and also a very circumstantial account of one, which being introduced into the rectum, in the time one could say a *Pater Noster* and an *Ave Maria*, passed upwards to the stomach and was vomited. In truth the very name of suppository is derived from the fact that it supplanted (supponere) clysters.

De Graaf also devised a special syringe with a flexible tube, to make which he used at first a bird's intestine, but afterwards leather, either of them a poor substitute for our modern rubber tubing. A modification of this tubing also served him for direct transfusion of blood. For this purpose he proposed the bird's intestine, terminated at each end by a quill for insertion into the bloodvessels. Verily, there is nothing new under the sun!

The present edition is beautifully printed, and is ornamented with sundry little tail-pieces appropriate to the subject, chiefly the syringe, the bed-pan, and the *pot de chambre* not infrequently in use by little winged cherubs; but in one instance, a little Cupid, hastening towards the too-distant vessel is evidently in the greatest danger of a lamentable accident from vesical overflow—the less threatening, however, since he has no clothing to speak of, the injury to which could excite maternal wrath.

CORRESPONDENCE.

A PLEA FOR BLOODLETTING.

To the Editor of The Medical News.

Dear Sir: Amongst the editorials in The News for September 16, in reference to "the Treatment of Acute Sthenic Pleurisy," I notice the query: "In view of the above, may we not inquire if it has been wise to abandon venesection altogether in cases of acute sthenic pleurisy? Have not effusions, serous and purulent, been more frequent and extensive since venesection has not been employed?"

So far as my observation and experience extend, I am prepared most decidedly to answer the latter in the affirmative. To my mind, the inquiry is opportune. The inquiry should be generally circulated throughout the profession: "Have we acted wisely and honestly in altogether abandoning general bloodletting, not only in the treatment of acute pleurisy, but in many other diseases assuming a like sthenic aspect?"

When I entered upon my professional labors, a physician was regarded as deficient in his *armamentarium* without lancet and cupping instruments. But the adage, "Better be out of the world than out of fashion," has shown its full force when applied to the medical profession in this particular. Fifty years ago, about the time of my pupilage, bloodletting was the panacea of the age; its use was not confined to the medical man, but the 'squire, blacksmith, etc., were prepared to bleed in emergencies!

It is not surprising, therefore, that venesection, under such circumstances so indiscriminately used by those too altogether ignorant of the laws of health or disease, should have fallen into disrepute, but it does not logically follow that it should be consigned to a grave among the "lost arts."

I have in mind a number of instances, coming within the compass of my own observation, of cases contemplated in the query. While practising in Oskaloosa, Iowa, some twelve or more years ago, pleurisy, pneumonia, and pleuro-pneumonia were quite prevalent in that locality. Many were treated by physicians who, according to "fashion" had discarded bloodletting as a therapeutic agent altogether, some of whom, particularly those of the younger members, had never witnessed phlebotomy. These cases generally progressed slowly, attended often with alarming sequels—sometimes necessitating paracentesis—others were treated from the onset, energetically by bleeding, either general or topical, or both; not a single case thus treated, to my knowledge, was followed by those distressing conditions. The contrast was very marked. Subsequent experience and observation have served to establish and confirm my conviction, that in the neglect of this therapeutic agent physicians often fail to give their patients the best means of relief and recovery. Respectfully,

J. P. Gruwell.

Salem, O., September 28, 1882.

POISONING BY BOSCHEE'S GERMAN SYRUP.

To the Editor of The Medical News.

Sir: The following case may be of interest to the profession. A short time ago, I visited a patient at about 10 A.M., and while examining him, my attention was called to an infant three weeks old, whom the mother said was dying. Upon hasty examination and inquiry, I was at a loss to account for its alarming condition; but being struck by its marked cyanotic appearance, slow respiration—three or four a minute—contracted pupils, responding sluggishly and feebly to light, and pulselessness, I asked the mother if she had given it anything. She replied that on the afternoon of the previous day she gave it three or four drops of Boschee's German Syrup for a "slight cold" it had had for a day or two. This statement of the mother at once threw a flood of light upon the case, as the symptoms were undoubtedly those of opium poisoning. The alarming symptoms came on about an hour after the administration of the syrup, and had continued ever since. The child had always enjoyed good health, excepting the "slight cold" already referred to. There was no discoverable pulmonary or bronchial lesion. Atropia and stimulants produced a slight but transient improvement in the symptoms, and the child died in a few hours, about thirty after the administration of the syrup. Respectfully,

H. C. Shuttee.

West Plains, Mo., September 12, 1882.

NEWS ITEMS.

Mississippi Inspection Service.—This service, which was instituted for the season by the National Board of Health in May last, was discontinued on September 30th. It consisted of a supervisor in New Orleans, whose duty it was to investigate and report upon suspicious cases of fever occurring in the city, and to announce the presence of yellow fever immediately on its recognition. The Board of Health of Louisiana pledged itself to afford this officer facilities for the performance of his duty. The dread with which yellow ever is regarded in the Mississippi valley is such that even a rumor of the disease in New Orleans is followed by depression and relaxation of business interests. The suppression of false alarms was a material gain to commerce, and was recognized by the State Board, although it is said that in a suspicious case which was investigated on September 12th, it failed to redeem its pledge to the supervisor of the National Board. While commercial interests, on the one hand, derived benefit from the presence of this officer, neighboring States looked to him for a notification of the existence of real danger. Under his supervision inspections of freight on river-boats and railroads were carried on, the certificate of inspection being to the trains what a clean bill of health is to a vessel arriving from a foreign port. It permitted immediate entrance to what would otherwise have been quarantined. The railroad companies so appreciated the value of this system of inspection as subserving their interests while acting as a guard to the people of other States that the expenses incurred were voluntarily borne by them. Vessels leaving New Orleans for ports above were inspected on the request of the master or owner, and certificates furnished of freedom from disease. These were accepted by local boards, and commerce was uninterrupted. When a vessel sailed without a certificate she became subject to the quarantine laws of the place of her destination. At Vicksburg and Memphis, by request of the local authorities, inspection stations were established to intercept vessels without certificates and verify the condition of those which passed them. This system of guard and pass-port enabled the people of the great Valley to pass the summer with a feeling of security.

The Yellow Fever.—The epidemic in Pensacola appears to have reached its height, as there has been, during the week, no daily increase, as heretofore, in the number of cases. Up to and including September 25, there had been recorded 517 cases and 54 deaths. There were on

Dates.	Cases.	Deaths.
September 26th,	60	2
" 27th,	60	6
" 28th,	42	2
" 29th,	52	11
" 30th,	53	3
October 1st,	45	4
" 2d,	46	5
Total,	875	87

The ten-per-cent. death-rate is somewhat heavier than that recorded in Brownsville; but an elimination, if such were possible, of the simple malarial cases which undoubtedly swelled the yellow-fever lists in the latter city, would probably show that the disease has not been more fatal in one locality than in the other.

Vaccination of School Children.—Dr. John H. Rauch, Secretary of the Illinois State Board of Health, has just issued a circular to County Superintendents, School Boards and Teachers, in which he calls attention to the fact that communications received since the beginning of the present school year, indicate the necessity for renewed instructions concerning the School Vaccination Order of the State Board of Health, promulgated in December, 1881.

The order has been complied with to a very gratifying extent. Its wisdom and utility have been demonstrated by the facts—

First.—That among the thousands of cases of smallpox which have occurred in the State since the order was issued, not one is reported of a public scholar who had been properly or recently vaccinated. Several cases, however, with a large proportion of deaths,

have occurred among scholars who had either not been vaccinated at all or not since infancy.

Second.—That in no instance where the order was thoroughly enforced has it been necessary to close the public schools, even when smallpox existed in a community. On the other hand, schools have been broken up and studies interrupted in a number of instances where—as shown by the returns in this office—the order had been neglected.

In some of these latter cases the failure to enforce the order was due to causes which no longer exist. The present is a very favorable season of the year in which to vaccinate. Good vaccine matter can be readily procured, and the operation is not now liable to be complicated by the results which obtain in cold and changeable weather.

Concerning the statements sometimes met with—of serious results from vaccination, loss of arms, and even death—the Secretary takes occasion to say that he has made it his personal duty to investigate every report of the kind which has come to his knowledge. The net result of such investigations is that not one such report has been substantiated. He has been wholly unable to find any evidence of a death caused by vaccination, in this State, or even of permanent injury or serious illness, due to the operation alone. He does know, however, of hundreds of deaths—aside from the suffering, the loss of sight, and the disfigured faces among survivors—caused by the neglect of vaccination.

An examination of the reports thus far received shows that more than two-thirds of the total school population of Illinois, were unprotected against smallpox on the 1st of December, 1881.

Of the two million vaccinations within the past eighteen months, over thirteen hundred thousand have been performed since the 1st of January, 1882, as the result mainly of this vaccination order, and of similar measures instituted by the State and local Boards of Health. Until these measures were fairly under way there was a steady increase of the smallpox—but coincidently with their successful operation came the decline of the disease, until now it is practically at an end in Illinois.

It remains now to perfect and perpetuate the results thus far accomplished, and to this end—so far as the public schools are concerned—the following instructions are issued with reference to the School Vaccination Order:

At the beginning of the school year teachers must satisfy themselves of the vaccinal status of each of their scholars.

Proper vaccinal protection means a successful vaccination in a child not yet arrived at the age of puberty; or, if beyond that age, a successful vaccination or revaccination, as the case may be, performed within the past two years (approximately).

Vaccination returns, accounting for every child whose name appears on the school schedule, must be forwarded to the office of the Secretary of the State Board of Health at the end of the second month of the school year.

Semi-centennial Anniversary of McGill University.—The medical faculty of McGill University celebrated its fifteenth anniversary on October 5, 1882.

Trouble in the Medical College of Virginia, Richmond.—Governor Cameron, of Virginia, a few days ago appointed a new Board of Visitors for the Medical College of Virginia, in Richmond, thereby summarily displacing the old board, which action created considerable excitement in medical circles. The old board, however, upon legal advice determined to hold on, claiming that the Governor under the law had no right to remove them; that he could only fill vacancies, and that no vacancies existed. On Friday, September 29, we learn from an Associated Press dispatch, after being commissioned, the new board proceeded to the medical college for the purpose of meeting and organizing, but they were denied admittance to the building by Dr. J. B. McCaw, dean of the faculty, who refused to recognize their right or authority. They therefore held a meeting in the college yard and elected Lieutenant-Governor John F. Lewis president, and Dr. Lewis Wheat, secretary. The demand for admittance was renewed and insisted upon by President Lewis, when the policemen who were present, at the instance of the faculty, took him into custody and proceeded to the first police station, accompanied by the remaining members of the new board. When the parties were brought before the Chief of Police no one appeared against them and he promptly dismissed the matter, as there had been no violence or breach of the peace.

The board then went to Ford's Hotel, where, after a few minutes of informal conference, it adjourned until 4 P.M., at which hour it reassembled. After an interchange of opinions, the desire seemed general to temporize and overlook the indignity offered the board, in view of the public good resulting from the full operation of the college in all its departments. Expressions of opinion indicated also a desire to divest the matter of all political significance as far as possible. A committee was appointed to lay the matter before the Governor, and the board then went into secret session. Upon the return of the committee from the Governor it submitted a preamble setting forth the occurrences, together with a resolution notifying each member of the faculty of the Medical College of Virginia that the board would proceed to consider whether each of them—the faculty—shall not for his participation in the illegal proceedings above mentioned be removed from his position as professor in said college. The resolution was adopted and the board adjourned to meet the following day.

On September 30, the new Board transacted business as if it had full possession of the College. Committees were appointed to take a full inventory of the College property, and to report a plan for the reorganization of all its departments. A resolution was discussed looking to a suit against the city of Richmond for damages for the false imprisonment of the President of the Board, Lieutenant-Governor Lewis.

The Seney Methodist Episcopal Hospital in Brooklyn.—The corner-stone of this hospital, to which attention has already been called (see The Medical News for March 11, 1882, p. 280), was laid on Wednesday, September 20th, with appropriate ceremonies. Dr. L. S. Pilcher, of the Building Committe, delivered an address on the occasion, from which we make the following extract:

"The evils of hospitals have been traced to five sources, overcrowding, defective ventilation, defective sewerage, uncleanliness, and failure to destroy the special poisons produced in the bodies of the sick. The last two sources become subjects to be provided against in the administration of a hospital, but the first three are to be the controlling ideas to be considered in its construction.

"Whoever undertakes to build a hospital has, therefore, a responsibility, which he cannot decline, to secure in its construction every possible safeguard against these sources of evil. Every hospital committee should be summoned before the bar of public opinion, and their work tried by the tests of hospital hygiene that modern science has established. In the old republic of Rome, when the interests of the State were commit-

ted to the care of the consuls, the charge that was given them was, 'Let the Consuls look to it, that no harm befalls the State.' In our modern republic, when the interests of the sick are to be committed to the authorities of an hospital, a similar charge might well be incorporated into every hospital charter. The hospital professes to do good; let its managers look to it that no harm befall its inmates!

"This reponsibility has been deeply appreciated by the committee to whom the duty of elaborating the plans of this hospital has been assigned, and particularly by the medical members of the committee, whose judgment and wish, in every particular, have been regarded in the plans of the hospital. It give us pleasure to publicly testify to this fact, and especially to acknowledge the willingness and ability which the architect of the hospital has shown in carrying out our suggestions.

"The central thought which has run through all the plans has been that of *isolation*. Each building is isolated, each room in each building is isolated, and, to a very great extent, each bed in each room is isolated. No ward will contain more than twenty-four beds, and there will be no bed upon which the direct rays of the sun may not fall at some time during the day. Every bed will enjoy at least 1,800 cubic feet of air-space, and not less than 4,800 cubic feet of fresh air will be supplied each hour to every bed, while the temperature of the air-supply will be under the control of the occupants of a room or ward; the amount of air supplied will be constant and beyond the possibility of being interfered with. The systems of fresh-air supply and foul-air removal for each ward are entirely independent of any other ward, and no one will be able to pass from one ward to another, even when the wards are in the same building, without first going into the open air. Perfect isolation, and insulation and ventilation of the water-closets has been provided for. As the sick are isolated from each other, so the well are to be isolated from the sick. The apartments for the attendants, when not on duty, and for the resident physicians, are isolated and ventilated with equal care.

"This is neither the time nor the place to enter upon the details of the plans which have been elaborated. The hospital, when completed, will afford generous accommodations for over 200 beds.

"This building, the corner-stone of which we are assembled to lay, is the central building of the group of buildings which are to constitute the hospital. In addition to the usual administrative offices and quarters for the officers of the hospital, it will contain a special ward of ten beds, and eleven private rooms, with accommodations for twenty-five beds. On its upper floor will be dormitories for the corps of nurses, and in the wing upon its eastern side are the chapel, museum, and library-rooms. In a separate building in the rear will be placed the steam-boilers, the laundry, the bakery, the kitchen, the apothecaries' department, and the servants' dormitories. On either side of the central buildings will be aligned the pavilions in which the common wards will be placed, four in all, the two nearest the central building containing two stories of wards; the one to the extreme west one story; that to the extreme east two stories, and to be especially modified to adapt it for a children's hospital. The nearest proximity of any of these pavilions of wards to one another will exceed 120 feet. Separate buildings will be provided for the surgical operating theatre, and for the mortuary.

"The institution, the character of whose buildings I have now outlined, will lack nothing in the scope of its design, the comprehensiveness of its details, and the perfection of its finish, to make it the complete embodiment of the Christ-given idea of relief to the suffering. It will be unexcelled in point of architectural beauty by any similar institution in this or any country. It will be free from the reproach of hospitalism, and will afford every facility for the cure of disease and the advancement of scientific medical knowledge. To all men alike who are sick and in need will its privileges be extended. Its crowning glory will be that, in all its ministrations and offices, it will name the name of Christ. In the laying of this corner-stone those who have for many months been carefully considering and maturing the plans for this great institution may well feel a special exultation, and be pardoned for expressing it. This act marks the beginning of the end, when of all these stones each shall have found its place, and when the completed structure, a perfect hospital, a true Hotel Dieu, shall stand forth, a magnificent example of Christian benevolence, a monument which shall render imperishable the name of the man whose munificence has built it, and which shall likewise forever testify to the world the charity of the Church which gave him birth, and to whose care he has committed the management of such a trust."

PERSONAL.—Prof. Wm. B. Carpenter, the well-known physiologist, and Dr. Morell Mackenzie, were present at the opening of the medical courses at the University of Pennsylvania and Jefferson Medical College, in this city.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending September 23, 1882, indicate that influenza has increased, that cholera morbus has considerably decreased, and that neuralgia, dysentery, cholera infantum, diarrhœa, diphtheria, whooping-cough, and intermittent fever have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending September 23, and since, at 21 places, scarlet fever at 8 places, measles at 1 place. Smallpox was not reported from any locality in Michigan.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 25 TO OCTOBER 2, 1882.

MIDDLETON, P., *Assistant Surgeon.*—Granted leave of absence for one month, on surgeon's certificate of disability, with permission to go beyond limits of the department.—*S. O. 103, Department of Texas, September 20, 1882.*

CARTER, W. F., *Assistant Surgeon.*—Relieved from duty at Fort Concho, Texas, to report to Commanding Officer at Fort Stockton, Texas, for temporary duty as Post Surgeon.—*S. O. 103, Department of Texas, September 20, 1882.*

POWELL, J. L., *Assistant Surgeon.*—To report to headquarters Department of Texas, to temporarily relieve Assistant Surgeon P. Middleton as Post Surgeon and Attending Surgeon at Department Headquarters.—*S. O. 103, Department of Texas, September 20, 1882.*

SHUFELDT, R. W., *Captain and Assistant Surgeon.*—To proceed to Jackson Barracks, New Orleans, La., and report to the Commanding Officer thereat for duty.—*S. O. 93, Department of the South, September 26, 1882.*

POWELL, J. L., *Assistant Surgeon.*—Relieved from duty at Fort Stockton, Texas, and to report at headquarters Department of Texas, for temporary duty as Post Surgeon, San Antonio, Texas, and Attending Surgeon at Department Headquarters.—*S. O. 103, Department of Texas, September 29, 1882.*

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

CELL LIFE AND ANIMAL LIFE.

An Address delivered at the Opening of the Seventy-sixth Session of the College of Physicians and Surgeons, New York, October 2, 1882.

BY T. MITCHELL PRUDDEN, M.D.

GENTLEMEN: We are met to-night upon the threshold of the opening college year, as devotees to the science of medicine, and it is the cherished purpose of this college, with all the facilities which its position and scope, and five and seventy years of experience afford, to teach this science in an unostentatious, but liberal and comprehensive way, to earnest and faithful men.

It is a fact which is daily thrusting itself into greater and greater prominence, that the science of medicine is only a single department of the more far-reaching science of biology—a science which treats of *all* living things from the tiniest microscopic fungus up to man.

In the earlier days of medicine, the close relationship between man and other living things was not recognized. Man stood apart in nature, upon a pedestal of his own creating, related to other living things only as their master, and the explanation of the mysteries and wonders of his existence were sought exclusively above or within, and not beneath him. To-day we know, however much remains yet untraced, that his relations to lower beings are most intimate, and that if we would understand his most complex organization, we must approach him through the more simple forms of life.

Moreover, however we may stand related in opinion to the great question, whether there is not some inscrutable factor in man, by which after all he does differ in a most essential manner from all else in nature, we are perfectly agreed that, as far as they go, the physical and chemical, and other natural laws, reign with a dominance as supreme, and as inexorable in the human body as in the tree, the reptile, or the distant star, and in precisely the same way. The ray of light is refracted with no less precision in the human eye than in the water of the lake; the restless vibrations of the molecules are as true to their orbits in the human brain as in the block of granite, or the tongue of fire.

As a result of this conception, it is evident that the devotee to medical science must be very hospitable to the sister sciences, even on the ground of simple policy, for they are indispensable to the welfare of his chosen goddess, and it is only through their aid that he can worship acceptably at her shrine. This is a source of much embarrassment to medical educators, and it is getting to be very hard to know how to embrace in a curriculum devised for three short years all that is necessary for the successful prosecution of a course of medical study. Physics justly claims a hearing; chemistry stands at the very core and centre of all the vital processes; zoölogy shows us in her lower ranks the analogues and prototypes of man in structure and function, or even claims a proprietorship in us more intimate than this; and to-day botany, from that part of her domain which lies beyond the reach of the unaided vision, points out to us I know not what myriads of tiny monsters, which in varied guise of bacteria, micrococcus, bacillus, and all the rest are stretching out their poisoned fingers, demanding recognition with a persistency which *will* not be ignored, and which threatens to carry the whole world by storm.

Now what are we to do? To-day the question is not urgent, but to-morrow the machinery of college routine and duties will begin to move, and those of you who have been here before already know, and those whom we greet for the first time to-night will appreciate very soon, that the amount of material at your hands, the facts and thoughts presented to you day by day, which must be worked over and become a part of yourselves, will seem absolutely overwhelming.

The first thing is to understand precisely our position; we do not want or need to become zoölogists, or botanists, or chemists, or accomplished biologists, in order to be good physicians. It has indeed, I think, been abundantly demonstrated that special workers in these fields become far too much engrossed in the minutiæ of the themes which engage them, and perhaps too deeply penetrated with the precision and exactness of the methods which they employ, to permit of a devotion to that class of works and studies which the practical exercise of our profession demands. But it is also unquestionably true that an elementary training in general biology and its methods of research greatly facilitates a thorough comprehension of the principles upon which much that is taught in medical schools directly depends. And, practically, you will find that everywhere in those departments which are preparatory to the real business of your lives—the prosecution of the art of healing—in your anatomy and physiology, the facts elicited from researches on the lower forms of life make up a very considerable and important factor.

But it is chiefly to the elementary school and to the university that after all we do and must look for a systematic training in the elements of biology. The fact is that medical schools are simply technical schools, and it should be clearly understood that their first duty is to train physicians in the science and art of medicine as it exists to-day—to fit men to avert disease if possible, or to direct it to a favorable termination if they can, or, when the need comes, to lead the hopeless patient as painlessly and gently as may be to his rest. The point which I wish to urge here is that we ought to fully appreciate the importance to us, as medical men, of the researches and advances in these collateral and closely allied sciences, so that even though we may ourselves fail of a thorough elementary training in them, we may yet fully recognize their value for those who have still the opportunity, and whom we may perchance advise; and yet more, that we may ourselves be in a state receptive to facts which now and again will come to us from without, and which may throw wonderfully illuminating beams along our path if only we know their value.

You will find that at this college, those subjects which experience has shown to be most essential to the successful practice of medicine are arranged in a progressive series, so that each year finds its appropriate studies. And you will doubtless discover that with all due care in the systematic disposition of your time, and with all the energy and enthusiasm which the nature of our themes is so well fitted to inspire, three years are all too short for the acquirement of that knowledge which it behooves us to possess. And you

will doubtless acquiesce in the conviction which is becoming almost universal among medical educators, that a fourth year must soon be added to the systematic course of study, if we would keep pace with the rapid progress displayed in many departments of medical science.

It is my special purpose in this address, to show you by a few simple illustrations of a theme, which is very familiar to many of you, how potent is the aid which comes to us in the study of man, from the contemplation of lower forms of life, and with what readiness long series of apparently isolated facts crystallize around some guiding principle, which may be seen cropping out here and there all along the whole scale of living things, when once we bid our eyes to look so far.

In general anatomy we learn that the body consists of a bony framework, around which various tissues and organs are securely, and compactly grouped. When we have learned the size, shape, number, relations, and names of all these parts, our study of macroscopic or general anatomy is done. If, however, entering that department of anatomy known as histology, we trace the manner in which these parts are made beyond the point where the naked eye can avail us, we find that they are all composed of certain tiny organisms called cells, and that these cells are held together and associated by certain materials which lie between them, and which are the products of their transformations.

Just as the chemist has his atoms and molecules, to which in the last analysis he refers the properties which all known substances possess, and explains by differences in their nature and movements, the various chemical phenomena which matter exhibits, so we may refer both the structural features, and all the activities of the animal body back to the structure and activities of our elements—the cells. While the chemist, however, must infer the existence of his atoms from their deeds, armed with the microscope we can see our cells, observe the things they do, and definitely trace out their life history.

Cells are little masses of matter of peculiar chemical constitution and of varied shapes and consistence which at some time exhibit that complex of phenomena which we call life; and the life of one of the higher animals is simply the sum of the more or less independent but coördinated lives of the cells which compose it, all acting in harmony. Living things differ from the non-living in that they have certain activities through which their life is expressed. In the first place, they are capable, in spite of various opposing forces, of maintaining their individuality, and by holding a balance between waste on the one hand and assimilation on the other, a series of capacities arise, which we call nutrition, growth, and development.

Living things, in the second place, possess certain activities by means of which they are capable of producing new individuals like themselves; in other words, they are endowed with the power of reproduction.

Lastly, living bodies, in response to varied influences, are capable of *doing* certain things in the way of movements or of elaboration of peculiar chemical products, etc., and these are called their functions.

You will observe, Gentlemen, that in enumerating these activities, I have spoken of them not as characteristic of man or of any special animal or plant, but of living things in general.

All life finds expression in these ways. The means by which the living being does these things may be in one case exceedingly primitive, and in another very complicated, but this does not alter the essential character of the ends which it achieves.

If you tie a bit of muslin over a water faucet and allow the Croton water to trickle slowly through it for a few hours, you will find on removing it that a more or less abundant greenish scum has collected on the cloth. Wash this carefully into an open dish, and let it remain for a few days in a light warm place, and then examine the sediment under a microscope, and you will find a very celebrated creature. It is called an amœba. It looks like a little lump of transparent or slightly granular jelly. You will see it thrusting out portions of itself in the form of longer or shorter arms, and then withdrawing them and sending out others in another place, apparently in the most aimless way; or you may see it rolling itself over and over, or, if I may so say, flowing along, so that it travels with considerable speed. Perhaps some microscopic vegetable will lie in its way, and it will flow over and enclose this, and, after digesting portions of it, expel the residue from whichever side or surface of its body may be most convenient. If, in a quiescent condition, it be touched by an external object, you may see it move in direct response to the irritation. If you are fortunate in your observation, you may see a constriction appear around some part of the lump, which grows gradually deeper until a portion of the mass separates from the rest and crawls off on its own hook as a new and independent amœba. It has no lungs, and yet it breathes; no mouth, still eats; no definite shape, yet grows; no nerves, yet is sensitive; no sex, yet may give birth to endless progeny.

Now this amœba is one of the lowest and simplest of creatures, and is the type of a cell—a creature which is composed of a single cell, and all the activities which I have mentioned as characteristic of living things are exhibited in it. It is a perfectly independent being, doing everything for itself, and doing nothing particularly well, except, perhaps, performing the function of reproduction, which it does with such ease and nonchalance as leaves little to be desired. The young which it produces are just like the parent, single cells, and their very first post-natal act may be to give birth to other amœbas.

Now let us advance a step in the scale of being, to an animal composed of several cells. There is a little creature, one of the group of sponges, called Olynthus. Let us start with the ovum of the animal, which is a single cell, not very unlike the amœba in appearance. Under suitable conditions this cell divides as the amœba does, and two cells are produced, just exactly alike. They do not separate, however, as do the amœba's to become independent individuals, but remain fastened together; then each cell divides again, and these still further until we have a little mass of cells all looking alike, and the whole somewhat resembling a mulberry in shape. But now a change comes, the cells on the outside become longer than the rest, and little hair-like processes, called cilia, grow out from them and begin to vibrate to and fro, and acting like tiny oars propel the little creature through the sea. Presently the rest of the cells arrange themselves so as to form a central cavity, with an opening at one side, the whole looking something like a tiny cup. The animal now attaches itself to a sea-weed, or a rock, and no longer needing the locomotive cilia, they disappear; but as it can no longer travel, it can no longer seek its food, which must be brought to it. Accordingly, we presently find that through the sides of its body little holes appear, and the cells lining the central cavity lengthen and develop cilia, whose vibrations maintain a current of water through the body which brings with it oxygen and food. This is the adult Olynthus.

Now observe, if you please, what has happened in the development of this little creature. A single cell divided into several cells, at first all just alike, and all

doing the same thing, but soon, as if in response to the growing needs of the animal, certain of the cells developed a special apparatus, and special capacity for performing rapid movements, and this capacity was associated with changes in the form of the cells; a specialization which signalized its advance to a higher type of existence.

Just here we come upon the great principle, in a very simple form, upon which the enormous differences between higher and lower animals rest; the principle of the physiological division of labor in cells. The more perfect the individual is, the more elaborate do we find the expression of this principle.

The difference between the amœba and the Olynthus from our present point of view—that which makes of the latter a higher animal than the former—is that it has a certain group of cells set apart to do a special thing, to move rapidly; amœba moves, but not so rapidly nor with such directness. If another group of cells were set apart in Olynthus to do the digesting, no new cell powers would be developed which the amœba does not posess, the primitive assimilating power would simply be specialized and intensified, and the animal would have risen to a higher grade of being

It would not be difficult, did time permit, to trace the manner in which, as we pass upward in the animal series, certain groups of cells become more and more elaborate in structure as they assume higher and more specialized capacities. We cannot tarry for this, but will glance for a moment at the exhibition of this principle in the development of man. In man, too, life commences in a single cell called the ovum: a cell which, though harboring potentialities of the highest order, in many respects greatly resembles our little denizens of the Croton water. This cell, under suitable conditions, divides and sub-divides, forming a little cluster of cells all looking alike. Then these cells arrange themselves in layers, some of them assume special forms as they increase in number, and develop special capacities and group themselves to form the various tissues and organs of the mature body, which finally is formed of a grand community of coördinated groups of cells, some of which have acquired the power to do special things in the most perfect way, while others have remained in a condition of comparatively low organization. Let us look at two examples of these two types of cells from the adult body—first at certain muscle cells. These in the very young animal look just like many other cells; they are individuals, they are alive and their life finds expression, just as the amœba does, in certain activities, nutrition, growth, function, and reproduction. Presently they become longer than their neighbors, little striations appear along their sides, they grow long and narrow until at last they are little thread-like bodies with a very complicated internal structure, and are grouped in bundles to form the muscles as we see them with the naked eye. You already know or will soon learn the peculiarities of structure of these muscle fibres and how such elaborateness of structure is necessary for the performance of the work which they have specially to do; namely, the accomplishment of rapid and powerful movements. Now the capacity of the muscle cells for doing this work has been acquired, if I may so say, at the expense of some of the other capacities which they originally possessed in common with other cells. Thus the power of reproduction is in them almost if not quite completely absent. They can also no longer seek out and take up crude food but it has to be prepared for and brought to them and in order that this may be done, certain other cells in the body develop the power of elaborating a peculiar fluid—gastric juice, which helps to change the crude food so that it finally becomes fitted for the nourishment, among others, of the special workers, the muscle cells; other cells—the red blood cells—develop the capacity of bringing them oxygen and in doing so have lost many capacities which are possessed by lower forms. Other cells develop in a peculiar way to form the nerves by which all the various parts of the body are brought into harmonious action, and so on. Thus we see in the higher animals each highly developed cell working for the others as well as for itself and for the organism as a whole, only its chief endeavor is concentrated in some one special thing, and as a result of this concentration some of the more general cell powers are lost or diminished.

Now look for a moment, on the other hand, at a type of cells which have not undergone this marvellous change. Take the white-blood cells, or the connective-tissue cells, for example. These simply remain in a condition of low organization. They are nourished; they grow; they can reproduce their kind; and can slowly move, all apparently in much the same way that the amœba does, their reproductive power, if any, being their most marked capacity. That they have great potential capacities, and are of incalculable service in the economy we may assume, but have not now time to show.

These examples must suffice for illustration of the great principle of the physiological division of labor in cells.

We find a close analogy to this, although it seems almost too trite to mention, in the division of labor in society. In primitive conditions of society, each man gets his own food as best he can, builds his own house, makes his own furniture, if he has any; in a word, manages his own existence on a quite independent basis. As society advances the tendency always develops for different men to do special things, and one man hunts, another tills the soil, another cooks; one becomes a carpenter, another a cabinet-maker, a great many become doctors, and so on; each getting the benefit of the other's special skill, and in turn contributing his own. In this way the same end—the maintenance of the individual—is not only more easily but better accomplished. But this arrangement, although on the whole advantageous, involves the unsymmetrical development of the individual. The hunter will find it hard to make a bureau, and the cabinet-maker looses much of that acuteness of vision and steadiness of nerve, which the man who shoots his game retains. The cook would scarcely succeed in composing an essay on molecular vibrations, and the physicist would doubtless prepare a chop most vilely.

But this is by no means the only expression of this principle in nature. Back of the division of labor in society, lies the division of labor which is expressed by sex. In many of the lower animals, as you well know, both sexes are found in one creature, these are hemaphrodites; but division of labor supervenes, and in the higher animals the larger part of the burden of reproduction is thrown upon a class of individuals which become the females.

In some parts of the Atlantic, and in the Mediterranean, there is found a lowly organized animal, allied to the jelly-fishes, which furnishes one of the most exquisite examples of the division of labor.

In this creature, which is composed of many individuals, we have first a central hollow stem, at the upper end of this is a little bladder filled with air, which floats the community just at the surface of the sea. Arranged around the upper portion of the stem are rows of little bell-shaped structures, which have the power of drawing in and vigorously blowing out the water, thus moving the community; these are the locomotive individuals, they do nothing else. Further down the stem are various kinds of individuals crowded together: first those which have become spread out into broad

hard plates, beneath which the others can hide in danger; then come the eaters, which are furnished with a complicated stinging apparatus, by means of which they catch their prey, a mouth into which it is thrust, and a stomach and liver for digesting it. Again there are separate individuals having long tactile feelers, these are the more acutely sensitive members of the community. There are, further, those whose sole duty is to perpetuate the species, and of these there are males and females. The food which is caught and digested by the eaters, does not nourish them alone, but passing into the central hollow stem goes to all the rest.

The character and actions of these workers show that they have a certain individuality of existence, but that they are closely dependent upon one another, and the whole constitutes a single animal. The creature commences life like a common polyp with a long stem; simple buds are at first formed all looking alike, but gradually these become changed into the various forms which I have so hurriedly described. These creatures are called Siphonophores, and as they swim about form one of the most beautiful of natural objects.

But we need not look so far away from home among the lower animals for illustration of this principle. Among the bees and ants it is displayed in such varied and striking ways that the accounts given us of the habits of these creatures read like romances or like travesties of human society. In fact, turn where you will you find the same thing, not in animals alone, but in plants as well. The various parts of the flower—corolla, stamens, pistils—are all only modified leaves, modified in the first place in form to serve the cruder purposes of generation, and then in color and fragrance in answer to the more refined and varied needs of their existence. And it is essentially the same principle extended to the grouping of living beings on the globe and to those which have left their traces in the rocks, which is involved in the grand generalizations of the celebrated English naturalist and philosopher, whose death we have so recently been called upon to mourn.

It is not a little inspiring, Gentlemen, to find, as we slowly and painfully trace out the structure and functions of the various parts of the human body at the dissecting table, in the physiological arena, and under the microscope, that we need not to hold all the minute and multifarious details which we discover as so many isolated unresponsive facts, but that they are all expressions of great underlying principles, boundless as nature itself and instinct with the pulse-throb of the universe.

Did time permit, I should like to picture for you the character and destiny of some of the lower forms of cells, which we find in the human body; those which have not undergone that differentiation in structure and function which belongs to higher types; to speak of the marvellous potentialities which are dormant in them; to show you how their very simplicity of existence, the absence of special powers, and their boundless capacity for reproduction particularly fit them to become the conservators of the individual; to indicate what an important *rôle* some of them play in the healing of wounds and in the formation of new tissues; or rather, let me be more specific, and say that I should like to lay before you the reasons which we have for thinking that in the healing of wounds involving the more highly organized tissues, such as muscles, nerves, etc., it is not chiefly the cells of these tissues themselves which initiate and carry on the healing process, and form the new tissues which are to replace the old, but it is the lower forms which apparently play the leading *rôles*. And it is a curious fact that when the new tissues are formed in the adult body they do not spring at once in mature form into being, but pass always through developmental stages similar to those which are observed in the early formation of the embryo. So that we are not to think of the lower forms of cells in the body as insignificant, because under ordinary circumstances their being and performances are humble, and inconspicuous, for they seem to be ever ready, either resting quietly in their tiny nooks within the solid tissues, or driven restlessly in the rushing torrent of the blood, to assume again the lowly but active powers of embryonic cells, and begin the work of reproduction and repair. Then if we had time to scan the reverse of this picture, we might see in these lowly organized cells how, when the conditions of their existence are at fault, they may, loosing their benign and conservative character, become freighted with most malignant potency, and subtlety, or with overwhelming suddenness, lead the body on to disease or death. It might be interesting to see how in the domain of pathology, which is the department dealing with abnormal perturbations, and changes of these various cell communities, some of the gravest questions have ever been, and still are, in reality only due to the uncertainty which yet exists as to which cells have undergone the changes involved in the physiological division of labor, and which still retain the power of adapting themselves in structure and function to the changed conditions of disease. But for the elaboration of all these suggestions, there is no time to-night.

I cannot refrain, however, from reminding you that since the day when the importance of the cell as a morphological and physiological factor in the animal economy became an established acquisition of our science, its dignity has never ceased to grow. And that as under the illuminating genius of Rudolph Virchow, of which you have heard so recently in this room, the principles of a cellular pathology were formulated, so one day we may hope to hear the enunciation of the no less profound, and perhaps more strictly practical, doctrines of a cellular therapeutics.

If I have accomplished the simple purpose of this address, I have shown you that all the varied structures and functions of the body are but the combined expression of the structure and lives of the cells which compose it; all coördinated and working in harmony by means of a self-built cellular mechanism. That, starting with the type of the most simple of living things, a single cell, the finished organism is an aggregate of the progeny of the original cell, some groups of which have developed special forms and powers, in accordance with a universal principle in nature. That the doctrine of evolution, even should the record of the rocks be incomplete and perfect continuity in the grouping of living species fail, still finds epitomized in every animal and plant which has escaped from the primitive simplicity of the lowest forms, a most pertinent illustration and convincing proof.

These thoughts, which may to many of you be simply reminders of facts and principles long since your own, I leave with you in the hope that at least in a subsidiary way they may be of value to you as you labor in the acquirement of that wealth of practical knowledge and fund of power which it is the primary duty of this college to impart.

If you still should ask me of the practical bearing of all these and kindred thoughts and studies, a question which medical men are, I think, too prone to utter, I answer simply that it is truth, truth concerning themes around which our best life endeavors will circle; and though from the contemplation of such truths we may not return laden with facts or thoughts which find immediate application, we cannot fail to bring a breadth of view and wider sympathy which will make us more powerful in any work which lies at hand.

ORIGINAL ARTICLES.

ELASTIC TENSION AND ARTICULAR MOTION IN POTT'S DISEASE.

By M. JOSIAH ROBERTS, M.D.,
INSTRUCTOR IN ORTHOPÆDIC SURGERY AND MECHANICAL THERAPEUTICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

(*Read by invitation before the Tompkins County Medical Society, at Ithaca, N. Y., September 20, 1882.*)

Probably no plan of treatment in the whole range of mechanical therapeutics has ever attracted so conspicuous and wide-spread attention, or has ever advanced the interests of American surgery abroad, more than that known as Sayre's method of treating spinal disease. The rapid recognition by the medical profession throughout the civilized world of the practical advance thus made in the treatment of vertebral caries, should be looked upon with honest pride by every American physician and surgeon. Though fully appreciating the great value of this plan of treatment, and having obtained gratifying results from its use in a considerable number of cases, much clinical observation and careful thought convinced me some time since, that further improvements in the mechanical treatment of spinal caries were not only possible and desirable, but probably obtainable in the near future.

Without wishing in the least to detract from the credit justly due Prof. Sayre for the introduction of this simple method of treatment, but only with the idea of arriving at correct notions regarding its intrinsic scientific and practical value have I ventured to criticise it.

In an article published in the current October number of the *New York Medical Journal and Obstetric Review*, entitled "Non-uniformity of the Principles of Treating Pott's Disease as Taught by Prof. Sayre," I have called attention to the fact that the *aim* of treatment, irrespective of the extent of the degenerative processes, was to secure anchylosis of the involved vertebræ; that although "absolute rest," and the restriction of "motion of the parts diseased," are put forward as fundamental ideas in the treatment of this malady, not even an attempt was made to enforce them in caries of the spine in the upper dorsal or cervical regions; that while, in the treatment of the middle and lower dorsal spine, articular motion was abridged to a certain extent, it was practically unrestricted at the seat of disease by the jacket and jury-mast, when used in treating upper dorsal and cervical caries;[1] finally, that while voluntary articular motion was vouchsafed to diseased cervical vertebræ, all the healthy segments of the spine below the axillæ were doomed to months, perhaps years, of immobilization in so far as that is possible by the encasement of the body in a closely fitting plaster dressing from the crests of the ilii to the armpits. In a single sentence, that the same mechanical principles are not advocated for the treatment of spinal caries occurring above the axillæ that are so emphatically declared to be of prime importance when considering the treatment of this disease below that level.

The conclusions reached in that paper were, that there existed no valid reasons for a change in principles when treating different parts of the spine; that better results were obtained in the cervical region by elastic extension and voluntary articular motion, than by rigid extension and fixation, such, for instance, as is afforded by the plaster jacket in the middle and lower dorsal regions of the spine when applied during the suspension of the patient.

The explanation which I gave of the beneficial results obtained in the treatment of cervical caries by elastic tension and articular motion was that, owing to the elasticity of the traction force, the jar incident to locomotion was abolished, reflex muscular spasm was overcome, and the close approximation of the normal movements of the spine was rendered possible without the slightest irritation, notwithstanding the existence of the carious inflammation. The flow of the blood through the vessels is thus facilitated, especially through the capillaries, in which the effect of the diastole and systole is not felt. The efficiency of the respiratory function is also augmented. More blood and better blood, consequently more nutritive material, and that of a better quality, is furnished to the parts for the purpose of carrying on the repair of the diseased tissues.

A number of patients coming under my observation having spinal caries and treated by elastic extension and voluntary articular motion, have recovered in a comparatively short space of time, without anchylosis or deformity, and with as free and extensive movements as before the occurrence of the disease.

These brilliant practical results have led me to the conclusion that the aim of treatment in caries of the spine should no longer be the securing of anchylosis, but that here, as in the treatment of chronic inflammations of the ankle, knee, and hip, we should aspire to the restoration of the functions of the diseased joints.

Further stimulus to therapeutic experimentation in this direction is to be derived from certain comparative anatomical and physiological considerations, which I can not here detail. In order to furnish a clue to these however, I may state a well-known fact, namely, that the normal condition of the vertebral articulations like those of the extremities is such as to permit of more or less freedom of motion. The mobility of the various joints of the body, especially those of the lower limbs and of the spinal column is of great importance in the avoidance of concussion or jarring of delicate nervous structures, which would otherwise result from riding, walking, running, jumping, falling, etc.

Again, articular motion, both in the lower animals

[1] Another fact which I have observed in studying the mechanism of the jacket support is that, however carefully the dressing may be applied, considerable freedom of motion of the segments of the lumbar spine is always possible. Hence, by its use in the treatment of lumbar caries, "absolute rest" could not be afforded to the diseased vertebræ. This fact, however, does not preclude the possibility of obtaining good results from its use in these cases. On the contrary, in conjunction with the efficient sustentation afforded by the jacket in lumbar caries, articular motion becomes an important factor in bringing about a speedy cure, for reasons already given in the article above referred to.

and in man, like the analogous movements in plants, is of much greater importance than is generally supposed in the maintenance of a normal circulation, and hence, in supplying the requisite nutrition for the growth and development of the individual, and the carrying on of reparative processes in cases of disease.

It is, therefore, evident that Prof. Sayre in recommending the application of "the usual treatment of a broken leg" . . . . "to a carious spine,"[1] has not borne in mind the physiological condition of the parts involved in the two instances. By applying "a fixed dressing securing absolute immobility" to a broken leg, we promote as best we can the early re-establishment of the function of that member by bringing about anchylosis, or bony union of the fragments, thus restoring the fractured bony shaft to its original state of rigidity. But bony union of the vertebral articulations is not a normal condition, and, hence, to aim at such a result by treatment before anchylosis has begun, would be as unphilosophical and as unscientific as to aim at securing anchylosis in cases of chronic inflammation of the hip, knee, or ankle.

There still remains much evidence in favor of my position, which the limits of this paper will not permit me to adduce. Pathological observations, though they have not been as numerous as could be desired, furnish us with significant facts bearing upon this important subject. It is now pretty generally admitted that, at least in the great majority of instances, the carious process commences in the cancellous structure of the bodies of the vertebræ. So long, then, as the articular surfaces are not involved, surely there can be no reason for immobilizing the vertebral joints, if the pernicious influence of inter-articular pressure, due to reflex muscular spasm and superimposed weight, is overcome.

I wish now to briefly direct your attention to some apparatus which I have devised for the purpose of securing, at the seat of disease, continuous elastic vertebral extension and voluntary articular motion, together with the avoidance of inter-articular pressure and friction.

Without detailing the various clinical observations and experimental mechanical steps which have led to the adoption of a new apparatus for the treatment of cervical Pott's disease, I will at once submit to your notice the final result attained.

Fig. 1, from a photograph by Mr. James U. Stead, affords a good general idea of the appearance of the instrument when applied. As will be seen, it consists essentially of two encasements, an upper or cervico-cephalic, and a lower or cervico-trunkal segment. The superior one has a clasp under the chin, which can be opened or closed by means of a key, thus permitting of easy removal or reapplication. The inferior one is provided with a hinge posteriorly, and a clasp anteriorly. The surfaces pressed upon by these two enveloping segments serve as points for counter-pressure. Elastic linear extension of the cervical spine is effected by means of two strong spiral springs playing upon upright steel rods, which are placed on either side of the neck. The degree of elastic traction force which is exerted can be regulated at pleasure by the thumb-screws, which support the spiral springs on

FIG. 1.

the steel rods. The upright rods are provided with a ball-and-socket joint at their lower end, thus permitting of all the normal movements of the head to be made, while at the same time elastic extension is enforced. Rubber bands extending from a hook screwed to the upper end of the steel rod on either side, to the cervico-trunkal segment of the instrument serve as elastic stays. These bands are of varying strength, and by their use the head can be sustained in any desired position, or its movements directed and controlled.

By doing away with the spiral spring and substituting non-elastic stays for the rubber ones, rigid extension and fixation of the cervical spine could be more nearly realized than by means of most apparatuses designed for the treatment of these cases. Fig. 2, from a photograph, illustrates the inconspicuousness of the apparatus when the patient is dressed.

[1] Sayre on Spinal Disease and Spinal Curvature, London, 1877, p. 13.

This appliance leaves all the healthy vertebræ, as well as the muscles of the trunk, unrestricted. Muscular debility and retardation of growth of healthy vertebræ are thus avoided.

Fig. 2.

In the treatment of regions of the spine below the cervical, we have to descend at once to the crista ilii for a point against which to make counter-pressure. If the disease be not located inferiorly to the middle dorsal region, it is always advisable

Fig. 3.

to still make upward pressure against the inferior occipito-mental surface, as in the treatment of cervical caries. Hence the cervico-cephalic encasement is retained.

Take, for example, a patient having spondylitis of the middle dorsal vertebræ, resulting in a marked kyphosis, which is well illustrated in a case sent to me by Dr. F. Heuel, Jr. (*vide* Fig. 3, from a photograph by Mr. O. G. Mason). To carry out the idea of making elastic extension and affording lim-

Fig. 4.

ited voluntary motion to this region of the spine, I made use of the following method:

Being kindly assisted by Dr. George W. King, I carefully suspended the patient in the usual manner with a skin-fitting knit-shirt and "dinner-pad" applied, until the patient was made comfortable. While thus suspended it was incidentally determined that, having overcome the reflex muscular spasm, a very considerable amount of articular motion could be effected without causing the least pain or discomfort.

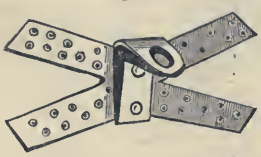
Having applied the first layers of plaster dressing, a head-rest of the form shown in Fig. 5 was placed in position and secured by an additional layer of plaster bandage. The action of this head-rest is the same as that previously figured and used in the treatment of cervical caries, the only difference being that the cervico-trunkal segment is replaced by metallic arms extending over the shoulders and connected with two shafts which pass down and forward under the arms, and are incorporated within the layers of plaster bandages. Four pairs of light steel perforated steps, made for me by Messrs. J. Reynders & Co. (*vide* Fig. 6), with thin sheet-copper arms attached, were next placed in position, one above the other, on the surface of the plaster dressing (*vide* dotted lines, Fig. 4), and secured in place

by a layer of bandage. These steps are for the purpose of retaining the elastic extension bars, presently to be described, in position.

FIG. 5.

Incidentally I wish to state that the relief afforded by suspension was so great in this instance, that within two or three minutes after being placed in the swing our little patient, who had for many nights previous been unable to sleep with any degree of comfort, fell into a sound slumber, from which he did not awake until he was removed from the apparatus to be laid on the air-bed.

FIG. 6.



After time had been allowed for the "setting" of the plaster, the "dinner-pad" was removed and a transverse circumferential division of the jacket

FIG. 7.

made at its smallest part (*vide* Fig. 4). The knit-shirt underneath was not divided.

Four light steel rods, turned up at one end as shown in Fig. 7 and provided with a nut and strong spiral spring, for making *elastic extension*, were placed and secured at their upper and lower ends by passing through the perforations in the projecting portion of the steps that are firmly embeded in the layers of plaster (*vide* Fig. 4).

FIG. 8.

With a wrench, Fig. 8, the nut may be moved up or down, and any desired amount of elastic extending force exerted. The improved position gained by suspension was thus maintained by continuous elastic tension. By moving up the nuts from time to time the kyphotic curve may be still further reduced, without producing the slightest irritation, while the jacket is *in situ*.

The amount of separation of the upper and lower segments of the jacket which it was sometimes found desirable to make exceeds the limits of elasticity on the part of the knit-shirt under the jacket. To obviate this, Mrs. Dawson, of the Brickford Knitting Co., made for me at my suggestion a shirt with an elastic zone, knit with covered rubber thread, opposite the point of division of the plaster encasement.

Should there be any spinal rotation the further advance of which it is desirable to prevent, or even overcome, this may be readily accomplished by means of one or more rubber guys passing from the summit of one steel rod to the base of another.

The testimony of several patients who have previously worn the rigid jacket, as recommended by Prof. Sayre, has thus far been to the effect that the divided one, with elastic extension bars inserted, affords more efficient support and is less irksome. That it is so is evident, for the same reason that a spring carriage is a more comfortable vehicle to ride in than a lumber wagon.

FIG. 9.

We have then for the treatment of the middle and upper dorsal regions, as in the cervical, an apparatus which exerts continuous elastic extension, overcomes reflex muscular spasm, and admits of limited articular motion at the seat of disease.

When the carious inflammation attacks segments of the lower dorsal or lumbar spine, the head-rest can usually be dispensed with and the bulge of the thorax be alone depended upon as the surface against which to make upward pressure.

To make the upper and lower segments of the jacket removable, Messrs. G. Tiemann & Co. have at my suggestion attached metallic clasps to them (*vide* Fig. 9).

The clasps of the upper segment are secured in position by strong bands of elastic webbing. This arrangement permits of the necessary expansion of the thorax with each inspiration, and at the same time does not invalidate the efficiency of the support. The clasp of the lower segment is secured by two nuts.

AN INTERESTING CASE OF HERPES IRIS.

By H. W. STELWAGON, M.D.,
physician to the philadelphia dispensary for skin diseases.

In the autumn of last year a case presented itself at the Philadelphia Dispensary for Skin Diseases, which in some of its features was of unusual interest. The patient, a boy, aged 14, was brought for advice concerning a peculiar eruption which had appeared a few days previously. An examination evinced the following: On the breast and upper part of the abdomen were twenty to thirty bright-red annular patches, varying in size from a pin-head to a quarter dollar, with the interior apparently free and of normal color; except the few vesico-papular points, all these patches were perfect rings. In the centre of each ring were the flattened remains of a papular or vesico-papular elevation. The rings were absolutely perfect as such, the band being about one line in width, and apparently made up of adjacent papules, which, however, had so coalesced that the band was one continuous wall. These when pricked emitted a small amount of serous fluid, disclosing their partly vesicular nature. A few of the rings were merely erythematous, devoid of any papular centre, on a level with the surrounding skin, and the color entirely disappearing upon pressure. On the dorsal surface of the arm and forearm were a dozen patches of the same character, except that the vesicular nature was still more evident. On the anterior surface were also a few rings and two or three erythematous spots. On the back, especially between the shoulders, were numerous annular patches. On the legs, anteriorly, were numerous papular points and small rings; also on the inner surface of the thigh anteriorly. This constituted the extent and character of the eruption when first seen, two days after its appearance—erythematous, vesico-papular, and vesicular rings, papular points, and a few erythematous spots.

There was no systemic disturbance, but on the contrary, the boy was in good health, evidently, however, a stranger to the bath. A few days later a second and a third ring had appeared outside of the first; several new ones also had arisen. Thus the case progressed for four weeks, the patches becoming confluent, especially those on the breast, where they so coalesced that there was but one large irregularly outlined patch, the interior showing the fading variegated colors of the original patches. Desiccation of the older rings ensued, as the outer rings appeared, and were covered with a thin scale. Indeed, there was very little crusting, except on the patches on the inner surface of the thigh. Here the vesicles had somewhat enlarged, and had become excoriated, and the process ended in slight crusting.

On the abdomen the patches remained discrete, and were formed of as many as five or six distinct rings, the outermost several inches in diameter, and in various stages of maturation and decadence. Those on the arm, legs, and back underwent the same changes, the patches consisting, however, of only two or three rings, and mostly of an erythematous, or, at the most, of a papular nature.

The colors were variegated and most beautifully shown, particularly in the patches on the abdomen and breast. Instead of seeming to be the result of disease, they appeared as if painted by the artist's brush.

At the end of the fourth week no new patches appeared, and the process gradually declined. However, it was not until more than three months had elapsed that all traces of the eruption had disappeared. As intimated, the disease ended in desquamation, rather than in crusting. There were no subjective symptoms. The case was of interest in several respects: the extent of the eruption; the exemption of the dorsal surface of the hands and feet, parts which are the favorite sites of the disease; the artistic display of color; the varied nature of the eruption; the large patches, composed of as many as six rings; and the duration of the affection.

ANEURISM OF THE ARCH OF THE AORTA SUCCESSFULLY TREATED BY IODIDE OF POTASSIUM.

By BENJAMIN RHETT, M.D.,
of summerville, s. c.

The value of large doses of iodide of patassium in the treatment of aneurism, is so well established that to record the treatment of aneurism of the trunk of any ordinary artery with that salt, would seem a work of supererogation. But I regard the case I am about to relate as sufficiently unique to justify its publication. At the date of treatment, February, 1875, I had never met with a record of a successful case of treatment of aortic aneurism by iodide of potassium; since that time I have seen one case of the abdominal aorta, if I remember aright.

The notes of this case were made at the time of treatment, with a view to future publication, after a sufficient time had elapsed to verify the permanence of cure (if cure it be), but were put aside and forgotten until a few days ago, when I examined the patient for a supposed return of her trouble, but could detect no signs of dilatation or pulsation in the locality of the aneurism.

In February, 1875, I was called to see Mrs. Catharine S., a colored woman of the better class, who seemed to be suffering great distress, partly due to nervous disturbance and partly to pain. She

gave the following account of herself, that fifteen or twenty years before she had an attack of inflammatory rheumatism; that from that time she had been more or less subject to rheumatic pains; that some time previous she had begun to suffer with what she supposed was beating of her heart, pain and numbness in her left shoulder and down her left arm on its inner side, also pain and numbness on left side of her neck and head, and a jarring sensation in the supra- and subclavicular spaces, and that these discomforts interfered with her sleeping. Although fleshy, she was pale, and had an habitually scared expression of face.

Upon stripping her, so as to lay bare the left shoulder and upper part of the thorax, a roundness or bulge at the root of the neck, and between the clavicle and scapula, was very perceptible, and pulsation of a heaving or billowy character in the part was plainly obvious to the sight. This pulsation conveyed to the ear a loud blowing (bruit) in the supra- and subclavicular fossæ, which was synchronous with the pulse at the left wrist.

As her disease had been pronounced by the physician who had charge of the case before it came into my hands, to be one of "heart disease" (so Mrs. S. informed me), I made a careful examination with a view to detect either valvular insufficiency or hypertrophy, but I could find nothing abnormal about the heart sounds; but I must say that these sounds were almost masked by the loud sawing bruit of the aneurism.

After careful investigation and due consideration of all the features of the case, I concluded that Mrs. S. suffered habitually from rheumatic gout, that she also had an aneurism of the arch of the aorta, and that the aortic wall had yielded at that portion where the left carotid and subclavian were given off. My reasons for thinking thus were that the numbness and pain extended not only down the inner portion of the arm, but up the side of the neck and head, and the locality of the aneurismal enlargement indicated this.

Operative interference was clearly out of the question, and although I looked upon any treatment as futile, I determined to try, as a *dernier ressort*, iodide of potassium, given in large doses, with a view to saturation of the blood, and with the very faintest hope, and no expectation, that coagulation in the aneurismal sac might occur, although I well understood that at a few inches from the ventricle the force of the blood current driven with powerful force, and almost direct impact upon the diseased walls, would be almost certain to wash away any coagula that might form within the sac.

The patient was advised to take, and did take, from 75 to 80 grains of iodide of potassium in syrup of sarsaparilla, as a vehicle, daily for six weeks, with decided mitigation of her trouble, but she complained so much of the scrapiness of her throat, and other ill feelings, that a short respite was given her, when she again used the same quantity of the salt for about a month.

Upon my last visit in 1875 an examination was made, when every sign of pulsation had ceased, and the pains in her shoulder, arm, neck, and head had undergone a decided mitigation, although not entirely relieved. Six months after I examined her again, and could detect no pulsation. Over seven years have elapsed, and being summoned to her, for supposed return of her trouble, I took the opportunity to examine again, and can detect no vestiges of the aneurismal bruit or dilatation. Being the subject of rheumatic gout, she suffers from gouty dyspepsia and reflex cardiac trouble, which led her to think that her aneurism was returning. She still complains of some pain and numbness down the inner surface of the arm.

When I took charge of Mrs. S. I found her accustomed to take digitalis, whenever she suffered exacerbations, which occurred from dyspeptic cardiac disturbance. She did this by the advice of her physician, and experienced considerable relief. As I have said, I concluded this cardiac disturbance to be reflex from gastric disorder. As I regarded the increasing the vigor of the heart's contractions by digitalis as not unattended with danger to the integrity of the aneurismal sac, I substituted monobromide of camphor, much vaunted at that time for such ailments, and found it perfectly inert, and Mrs. S. has continued to this day occasionally to use digitalis for this reflex cardiac disturbance, as she states, with advantage.

The result was so unexpected, that I have been at times tempted to doubt the accuracy of my diagnosis, but after carefully reviewing all the facts of the case, I cannot but come to the conclusion that this was a case of aneurism of the arch of the aorta, and that coagulation within the sac, and its subsequent obliteration, has been accomplished by the administration of large doses of iodide of potassium, kept up for a period of three months with a short rest, and that, if I am correct, the fact is worth putting on record.

APHONIA, WITH ABSENCE OF ARYTENOID CARTILAGES AND VOCAL CORDS.

By F. A. BURRALL, M.D.,
ATTENDING PHYSICIAN TO THE PRESBYTERIAN HOSPITAL, NEW YORK.

P. B., æt. 47, German, single, sailor, admitted July 18. Family history: Father died at the age of 81, mother at 64; causes of death unknown to patient; brothers and sisters living and healthy. Previous history: Patient has always been strong and healthy; fifteen years ago had Panama fever, but recovered entirely. Denies ever having had any venereal disease. His present illness commenced twelve months ago, when he caught cold and commenced to spit up a thick jelly-like sputum. Since then he has lost flesh and strength steadily, and has had night-sweats. He first became aphonic last month; has had pain in the region of the larynx for five months, which pain was increased by swallowing. The appetite is poor, the bowels generally regular.

On admission the patient had the appearance of having been a strong and robust man, but he is now bent and emaciated. He is weak, and seems to have lost all vigor and ambition. Appetite poor, bowels loose. He is probably anæmic, but this

condition is concealed by a decided bronze hue of the skin. The aphonia still persists. Physical examination would indicate the condition known as "fibrous phthisis," there being a general retraction of the chest-walls, dulness over the whole lung, and no moist sounds on auscultation. Ordered quinia, iron, and nucis vomicæ ext. in tonic doses, and good nutritious diet.

July 20.—The above drugs were discontinued, and in their place ordered spts. frumenti in a bitter infusion ℥ss t. i. d., also elix. ferri. phosp., quinia et strychnia, the dose to be gradually increased until the influence of the strychnia is apparent.

31st.—Since the last note the patient has been improving slightly, and his whisper seems a little stronger; the above preparations have not been used in large doses, as the system could not tolerate them.

August 1.—The patient's throat was to-day examined with a laryngoscope. At this time he told of spitting up five or six minute bodies, which he compared to small pieces of square matches half an inch long. The examination showed that the epiglottis presented a peculiar appearance, being, as it were, folded upon itself or curled up laterally. The vocal cords and arytenoid cartilages were missing, and to this absence of organs his loss of voice is ascribed.

5th.—Patient's throat was again examined as above, and the same state of affairs confirmed.

18th.—Since last note the patient has gradually improved in his general health, but his local condition remains unaltered.

Aphonia may depend upon a variety of causes, such as hysteria, syphilis, the presence of a laryngeal tumor, swelling of the arytenoid cartilages, paralysis of the muscles attached to the chordæ vocales, and a number of other factors which prevent proper approximation of the vocal cords. With the laryngoscope the diagnosis of the cause is as a rule easy, since the larynx lies exposed before us and we examine its condition as we do that of other visible organs. Without it, the recognition of laryngeal disease is like guessing at the contents of a covered box, and with it, the cover is removed. The instrument is, however, regarded too much as the special property of the laryngologist, whereas it is, next to the thermometer, one of the most important instruments of precision which special study has shown to be necessary for general use, since while it often may be, and too often is, dispensed with, it is, for the proper diagnosis of laryngeal disorders, quite indispensable. With a fair amount of perseverance almost any practitioner may learn to use it, and the labor is amply repaid by the ready aid which it often gives.

The above case illustrates the usefulness of the laryngeal mirror. Until the loss of the organs on which speech depends was demonstrated, it was impossible to know the reason of the aphonia, but that being known, the futility of treatment became apparent. Doubtless those who confine their treatment to throat diseases alone, acquire superior dexterity and knowledge, which have their great use in certain cases, but the idea that there are great difficulties in the use of the instrument leads many to preclude themselves from a means of information which it is not an exaggeration to say should be at the service of all general practitioners.

48 West Seventeenth St.

MEDICAL PROGRESS.

The Treatment of Polydactylism.—One or more supernumerary digits, or polydactylism, is one of the most frequent of congenital deformities. It presents, however, considerable variety in its nature. In some cases there is only a mere rudiment of a finger or toe, consisting of skin and fibro-cellular tissue with usually a small piece of cartilage in the centre, adherent to one of the fingers, and more common on the inner than the outer side of the hand. In some cases the digit is perfectly formed, and articulates either with the shaft of a phalanx or a metacarpal bone of another digit, sometimes in common with the normal finger, with a broad head of a metacarpal bone, or in still rarer instances, upon one extremity of a bifurcated metacarpal or metatarsal bone. Cases are also met with in which the additional finger or toe has been united along its whole length with the next digit—a combination of polydactylism and webbed finger. Where the digit is a mere rudiment, it is always an unsightly and useless appendage, and should be removed at quite an early age by division of the pedicle with the ligature, knife, or, as recommended by M. Polaillon, the galvanic cautery. Where, however, the digit is fully formed, and supplied with muscles, so that it shares in the movements of its fellows, it becomes a question whether it should be removed, the answer to which depends upon the utility of the supernumerary digit and the extent of the deformity occasioned by it. The removal of these digits is a perfectly simple operation; but when they articulate with a metacarpal bone within the same capsule as the normal digit, there is a danger of exciting inflammation in this joint, and of so causing anchylosis. To obviate this M. Sédillot advised that in such cases the amputation should be made through the base of the digit to be removed, so as to leave the articulation intact. This plan has been generally adopted of late years, but there seem to be reasons for modifying Sédillot's advice. In the first place, we are now enabled to open healthy joints without exciting inflammation or running the risk of anchylosis. And in at least three cases the base of the digit left behind has subsequently grown, and in part reproduced the deformity. M. Chrétien, to whom such a case has recently occurred, has suggested that the explanation of this is that the base of the phalanx is ossified from a separate epiphysial centre, and that when the amputation is so performed as to leave the epiphysis unimpaired, it may continue its independent development. In the rare cases of a bifid metacarpal bone, the amputation should be made at the point where the shaft of the bone bifurcates. There is, of course, less reason for undertaking any of these operations in the foot than in the hand.—*Lancet*, September 23, 1882.

Abdominal Typhus in Children.—Dr. Röth (*Arch. f. Kinderheilk.*) reports his observation on eighty-two cases of this disease in children under fifteen years of age; twenty-nine of these were in the children's hospital, and fifty-three at the poly-clinic at Heidelberg. Under one year of age, there was one child, nine from two to five years, thirty from six to ten, and forty-two from eleven to fifteen. Of the eighty-two cases, eight ended fatally, and two others

died from relapses. In a minority of the cases, the disease was ushered in by a chill, after which the temperature rapidly increased. In the majority the incubation stage lasted from three to seven days, then followed, as a rule, febris continua remittens, which lasted from six to twenty-five days, with evening rise of temperature to from 39.5° to 40°. Finally there was febris intermittens, lasting from four to five days. The spleen was enlarged in sixty-two cases, but there was no enlargement discoverable in some of the most severe cases. The roseola appeared between the sixth and eleventh day and was tolerably constant. In some it was very slight and transient, continuing scarcely a day. In others it failed wholly. In forty-three cases its presence was doubtful; in thirty-seven it was unmistakably present. In forty-six, bronchial catarrh was a complication; in seven, bronchitis and broncho-pneumonia. There were eight relapses, five slight, and three severe, of the latter, two died.—*Physician and Surgeon*, October, 1882.

EXTRA-PERITONEAL NEPHRECTOMY.—Under this title DR. L. BRICHETTI reports an interesting series of experiments performed on dogs. All his cases (the number is not stated) recovered promptly; the author attributes his success to his precaution in not placing a clamp on the pedicle of the kidney, and to having ligated the vessels and ureter separately. His cases of experimental nephrotomy have been equally successful.

Brichetti advises the incision of the kidney, instead of nephrectomy, as advised by Billroth, in cases of suppuration of the kidney, such as follows gunshot wounds. Drainage and antiseptic injections will then constitute all the necessary after-treatment.

Nephrectomy should be reserved for renal tumors of a malignant character.—*L'Union Médicale*, September 23, 1882.

ETIOLOGY OF HEMORRHAGIC VARIOLA.—At the Rochelle Congress (*Gaz. des Hôp.*, September 5) DR. PETIT read a paper on this subject, in which he came to the conclusion that the visceral alterations found at the autopsy of individuals dying of it should really be regarded as the *causes*, rather than the effects, of this form of smallpox. The same may be said of other forms (usually termed malignant) of this and some other affections. It is necessary, however, to distinguish between two forms of the alterations observed, viz., those which are of old date, as degeneration, steatosis, sclerosis, etc., and those of recent origin, as interstitial hemorrhages. Visceral lesions, whether causes or effects of a morbid condition of the economy, act on variola as they do on traumatic lesions, by imparting modifications to the blood or tissues, and especially the capillaries. Among the subjects predisposed to hemorrhagic variola may be ranged those who have already suffered from diseases of the liver, spleen, kidneys, heart, and perhaps lungs, or from affections capable of producing serious change in these viscera, as rheumatism, scarlatina, paludism, alcoholism, pregnancy, etc. Although we may not be able to point to any therapeutical advantage derivable from these etiological conclusions, they may aid our prognosis when individuals, the subjects of these conditions, contract smallpox. Such cases will very probably exhibit the hemorrhagic form, or even some other still more serious one.—*Med. Times and Gaz.*, September 23, 1882.

MILK-POWDER IN GASTRIC AFFECTIONS.—DR. DEBOVE, in a communication to the Paris Hospital Medical Society (*Gaz. Hebdomadaire*, August 25), observes that the milk regimen, which is so indispensable in affections of the stomach, and especially simple ulcer, speedily becomes so disgusting to these patients that it has to be left off. This serious inconvenience, however, may be remedied by the employment of the œsophageal tube, now used for feeding phthisical patients. But by this only a litre of milk can be introduced at a time, so that it would require to be employed six times in order to introduce the six litres, which is the mean quantity required for the subjects of *ulcus rotundum*. To avoid this frequent introduction of the tube, Dr. Debove has had skimmed milk evaporated (cream being but slightly digestible), and the residue reduced to a fine powder. If this be dissolved in warm milk, two or three litres of milk may be injected in the same volume as a single litre. It is possible that this milk powder, which furnishes excellent results in gastric affection, may also prove very useful in Bright's disease, cardiac affections, and all cases in which a milk regimen is employed. About a litre of pure milk is represented by 120 grammes of the powder. Dr. Dujardin-Beaumetz observed that in feeding the subjects of phthisis with the tube he has obtained excellent results from a mixture of powder of meat, powder of blood, and powder of milk. As powder of blood is not very digestible, he only adds a small proportion of that as a ferruginous principle.—*Med. Times and Gaz.*, September 23, 1882.

TUBERCULOSIS OF THE TONGUE.—DR. THOMAYER, of Prague, describes three cases of tubercular ulceration of the tongue. In one a wide fissure existed about the middle of the dorsum, with yellow-coated base, and prominent coarse tubercular nodules at its margins. In both lungs there was widespread tubercular disease. In the second case the ulcer occupied the right half of the tip of the organ, and was characterized by numerous firm granulations in part of its base, the rest being covered by a thick yellow layer; the margins of the ulcer were also firm, beset with gray and yellow granulations. The ulcer bled slightly, and was not benefited by treatment. The third case was similar, only the ulcer was seated on the frænum. It was treated by the topical application of chloride of zinc, which produces only temporary benefit in the breaking down of the nodules. Microscopical examination was made of the diseased organ in the two fatal cases. The ulceration had destroyed the mucous membrane and submucous tissue, and the base was formed by a thick layer of small rounded cells, intersected here and there by muscular bundles. Beneath this layer, there spread into the intermuscular spaces masses of similar cells, which, under high powers, were found to consist partly of giant-cells, and to be separated by the delicate stroma of tubercle. Some isolated tubercles were found deep in the substance of the organ. The muscular fibres themselves seemed invaded by the cell-growth, which was not limited to the intermuscular spaces. There was proliferation of muscle nuclei and of endothelium of the bloodvessels. Dr. Thomayer says that the extent of the lesion demonstrates the futility of treating these ulcers by caustics, and points to the advisability of excision.—*Lancet*, September 23, 1882.

AMPUTATION OF THE SHOULDER.—In a case of osteosarcoma of the scapula, M. DEPRÈS has conceived and executed with success the plan of amputating the shoulder, that is to say, of removing the arm with the scapula and a portion of the clavicle. The dangers of this operation lie, 1st, in the great loss of venous blood; and 2d, in the entrance of air into the axillary vein; but these accidents are not infalliby fatal.

In the case operated on, syncope and foaming at the mouth occurred, but the patient recovered; the wound was healed in two months.—*Rev. Scientifique*, September 23, 1882.

A Case of Spontaneous Rupture of the Spleen.—Dr. F. M. Calkins reports the case of a woman, aged 45, who, being in usual health, was awakened while in bed, at about 1 o'clock in the morning, by a severe pain in the abdomen. She described the pain as tearing, as if something was giving way. Dr. Calkins was not called until 12 o'clock noon, and when he reached the bedside he found the patient pulseless and in a complete state of collapse. She rapidly sank and died one hour after his arrival. From the previous history, it appears that thirteen years previous to her death she had suffered severely from malarial fever, which resulted in an enlarged spleen. The splenic enlargement increased in growth for about three years, when it apparently ceased to increase in size. The tumor, as examined through the abdominal walls, was located in the region about midway within the left lumbar and inguinal spaces, and from its position had been previously diagnosed by some as ovarian tumor. The enlargement of late years had caused the patient but little trouble or anxiety. It sometimes at long intervals gave her a few hours of severe pain, but passing off left her apparently well.

A post-mortem examination was made twenty-four hours after death. Upon opening the peritoneal cavity a large quantity of blood was found, which, being removed and weighed, amounted to six and one-half pounds. A large blood clot was discovered in the left inguinal region, and, in attempting its removal, it was found to be attached to the lower and convex surface of the displaced spleen. The spleen was lying in the lower lumbar and upper inguinal regions. Upon its removal, a rent or tear was found upon its inferior and convex surface, measuring in length five and one-half inches. Its weight was two pounds and ten ounces, about six times its average weight. No microscopal examination of its tissue was made. Its peritoneal covering was, by inflammatory adhesions, attached to the abdominal wall showing previous local peritonitis. The other abdominal viscera appeared normal. The general appearance of the spleen did not indicate great softening, and its rupture was, in Dr. Calkins' judgment, due to over-distention of the organ by blood engorgement.—*Michigan Med. News*, Sept. 25, 1882.

Osteotomy and Tarsotomy in the Treatment of Congenital Club-foot.—At the meeting of the Académie de Médecine, held September 19, M. Jules Guérin read a paper on this subject, of which the following are the conclusions:

1. Tarsotomy, the ablation and resection of the tarsus to remedy club-foot, even when of the most serious character, is an operation which should be discarded as one of the most unjustifiable abuses of surgery.

2. This method results in a dangerous and useless mutilation of the foot, and should always be supplanted by the more scientific methods of tenotomy, syndesmotony, massage, and orthopædic apparatus.

3. Even in cases of inveterate club-foot in the adult this method is not preferable to the attempt to overcome the deformity by appropriate apparatus.—*L' Union Médicale*, September 21, 1882.

Ferruginous Livers.—The presence of an excess of iron in the livers of anæmic patients is a curious fact, of which several instances have been described in Germany. One case was described by Stahel: and Lindenlang, in the liver of a patient with purpura, found a considerable excess of iron. Marchand has lately described the liver of a phthisical patient, aged sixty years, which presented an unusual brownish-red color associated with evident cirrhosis. The microscope showed an infiltration of the hepatic cells and of the interstitial connective tissue by pigmentary corpuscles, which gave the characteristic test for iron with yellow ferrocyanide. A chemical analysis showed that the ashes contained not less than 30 per cent. of iron. It has been supposed that the excess of iron is the result of an abnormal destruction of red blood-corpuscles in the organ, but it is open to question whether it is more than the result of the free administration of iron by the mouth.—*Lancet*, September 23, 1882.

An Undescribed Disease of Infants.—Dr. Riga (*Movimento Med. Chir.*) has observed a pernicious disease of the mucous membrane of the child's mouth. It consists of the formation of a false membrane between the end of the tongue and the frænum. The membrane is round and small. Children, in whose mouth this appears, lose strength rapidly, refuse to nurse, and ninety per cent. of them die. The disease has been observed only in summer and is always associated with intestinal catarrh. It lasts from two to eight weeks. It is found in children only during the first dentition, it is not contagious, but appears to be infectious. In the Terra di Levoro the disease has been endemic for sixty or seventy years. During the past decade, there has been no diphtheria in that region. No scientific study of the disease or membrane has yet been made.—*Physician and Surgeon*, Oct. 1882.

The Alleged Digestive Capabilities of the White Blood-corpuscles.—Mr. E. A. Schaffer has made a number of experiments to settle this point, chiefly with the white corpuscles of the newt, and these have been tested with particles of proteid, of fat, and of starch, which in every case were suspended in salt solution. The proteid particles were in the shape of torulæ of yeast (which were presented to the corpuscles either in the living condition or after having been killed by boiling); the fat was in the shape of milk-globules; and the starch employed was obtained by washing the dough of wheaten flour with salt solution, and, after allowing time for the coarser granules to subside, taking a drop of the supernatant fluid containing the finest particles in suspension.

The general results of the experiments may here be briefly enumerated. In no case observed, although the period of observation extended in some instances to one or even two days, and was never less than five hours, did any particle entirely disappear by solution within the corpuscle. In some cases, the particles became surrounded by a zone of clear fluid, and, included in this, were moved about by the streaming of the protoplasm to different parts of the corpuscle; but, to all appearance, they remained unaltered. Exception may perhaps be made for the yeast torulæ, in which, in many instances, the distinction between the protoplasm and its included vacuole became obscured, but it was not possible to affirm that this was due to anything else than the lessened distinctness with which the torulæ could be seen in the irregular corpuscle. In the case of starch-granules, it was found that however minute they might be, and however long included, the addition of iodine solution always produced in them the usual intense blue color. It was noted, however, that the protoplasm of white corpuscles, which had retained many starch-granules, tended to be more deeply tinged by iodine than that of others which contained no starch, whence perhaps it may be inferred that a small amount of starch has undergone transformation into dextrine. On the other hand, it was not found that white corpuscles, which had been abundantly fed with starch, exhibited, on subsequent treatment with iodine, more of the claret-tinted protrusions indicative of glycogen than others which had not contained any starch-granules.

It is clear, from the generally negative character of the results obtained, that the assumption of the possession by indifferent protoplasm, and especially by that of the white corpuscle, of distinct digestive powers, rests upon an entirely insufficient basis of fact; and, although it is scarcely possible to prove that no change whatever occurs in the included organic particles, it may yet be affirmed that, if any change is produced, it is so slight in amount as to be altogether beyond the range of our present means of observation. Moreover, considering that the white corpuscle inhabits a medium which contains in solution all the elements necessary for its nutrition, there is, *à priori*, an improbability of its possessing the means of reducing them from the solid to the fluid condition.—*British Medical Journal*, September 23, 1882.

HYALINE DEGENERATION.—In the last number of Virchow's *Archiv*, DR. MAX VALLAT described in detail the process of hyaline or fibrinous degeneration of tubercular formations—a change which has only received full attention of late years, although it is not infrequent in other structures, especially in the wall of arteries. In tubercles, it is best observed in those which occur in the spleen, lymphatic glands, and liver, and is to be regarded as an early stage of caseous degeneration. Dr. Vallat concludes that it is formed from the reticulum of the peripheral zone of the tubercles, and also from the trabecular tissue of the spleen and lymphatic glands, the bands becoming thickened, homogeneous, and glistening, whilst the spaces between the original fibres become converted into narrow channels in which only the nuclei of the cells that formerly existed there remain. In the tubercle it also replaces the epithelioid and giant cells, the former appearing to be converted into homogenous non-nucleated masses. The precise share taken by the giant cells in the formation is unknown. The channels left between the degenerated and swollen bands allow of the passage of fluid and pigment particles into the interior of the tubercle. In caseating the material breaks up into a finely granular mass, and is often found to be beset with nuclei, either the relics of previously existing cells or immigrants from surrounding vessels.—*Lancet*, September 23, 1882.

CONTRIBUTIONS TO THE CHEMISTRY OF BILE.—The remarkable behavior of the galls of Tübingen cattle with ether and hydrochloric acid, has already been noticed by G. HÜFNER, (*Journ. Chem. Soc.*, August, 1882). It was thought that a study of the relative quantities of glycocholic and taurocholic acids in different samples of bile would explain why some crystallized at once on addition of ether and hydrochloric acid, and other kinds refused to do so. To this end, ten samples of bile were analyzed, six of which gave a rapid crystallization of glycocholic acid, one a weak one, and three none at all; it was found that the quantities of taurocholic and glycocholic acids respectively were as one to five in the samples from which the latter acid crystallized rapidly, and about equal in those where no crystallization at all occurred. That this result had nothing to do with the question as to the absolute increase or decrease in quantity of each acid in the bile was shown by the fact that dilution in the one case did not put a stop to crystallization, whilst in the other concentration did not induce it.

Again, experiments with mixtures of the pure salts of taurocholic and glycocholic acids showed that the relative proportion of two acids present in solution together had very little, if any, effect on the crystallization of the latter. Hence those biles in which there is no appearance of crystallization of glycocholic acid on addition of ether and hydrochloric acid, must contain some other body, the presence of which is possibly dependent on the nature of the animal's diet, and which prevents the crystallization of glycocholic acid under those conditions.—*American Journal of Pharmacy*, Oct. 1882.

VACCINE CHARBONNEUX.—From the subjoined report it will be seen that Dr. Klein has arrived at conclusions—based upon comparatively few experiments, it is true—adverse to the general adoption in this country of Pasteur's proposal to inoculate cattle with anthrax as a prophylactic measure against that disastrous disease. The report has been communicated to the Veterinary Department of the Privy Council by the Local Government Board, and is published in the current number of the *Veterinarian:*

"Vaccin charbonneux is to be obtained, and is announced to be obtainable (in the *Farmer*), from M. Bontroux, agent of M. Pasteur in Paris (applicants to M. Pasteur are referred to M. Bontroux), and, as I happen to know, it is brought over and sold and used in considerable quantities. The 'vaccin' is sold in tubes (each containing enough lymph for the inoculation of one hundred sheep or fifty cattle) as 'premier vaccin charbonneux' and as 'deuxième vaccin charbonneux.' The 'premier vaccin,' according to the printed directions accompanying each lot, is inoculated first; after a lapse of twelve to fifteen days the 'deuxième vaccin' is used in the same manner. The animals thus twice inoculated are supposed to immune against fatal anthrax. I have obtained through two independent sources two lots of this vaccin charbonneux (premier and deuxième), and have tested them by experiments. The results of these experiments enable me to say—(*a*) animals inoculated with this 'vaccin' (premier and deuxième) are not made immune against fatal anthrax; and (*b*) both the first and second vaccin may produce fatal anthrax. The following facts prove these propositions:

Experiments with Lot A.—Inoculated with 'premier vaccin,' two sheep, two guinea-pigs, and two mice; no change in any animal. Inoculated with 'deuxième vaccin,' the above two sheep and the above two guinea-pigs. One of these sheep showed rise of temperature, and falling off in food for the first two days after this second inoculation, but was all right again after three days. The two guinea-pigs were dead of typical anthrax within forty-eight hours. The above mice were inoculated with the blood of one of these guinea-pigs. Both mice were dead of typical anthrax within forty-eight hours. The two sheep having been inoculated with the premier and deuxième vaccin ought to have been immune against fatal anthrax. Now see what happened: according to M. Pasteur, the *Bacillus anthracis* of blood of an animal dead of anthrax, when cultivated at 42°–43° C. for twelve days, loses all virulence and becomes thereby converted into 'vaccin.' I had grown the *Bacillus anthracis* of blood of a guinea-pig dead of anthrax at a temperatnre of 42°–43° C. for *twenty-one days*, and with this culture I inoculated the above two sheep. The result was that both animals were dead of typical anthrax within forty-eight hours.

Experiments with Lot B.—Inoculated with 'premier vaccin' four guinea-pigs and six mice. Within forty-eight hours three of the guinea-pigs and three of the mice were dead of typical anthrax. My method of using the fluids for inoculation absolutely precludes any accidental contamination, and hence these results must be accepted as perfectly reliable. This country is comparatively free from anthrax, and therefore the introduction and use of this so-called 'vaccin charbonneux' seems to me most dangerous, and capable of producing incalculable mischief."—*Lancet*, September 23, 1882.

The Digestion of Drugs.—Therapeutists have paid little attention to the changes which drugs, administered by the mouth, undergo in the digestive organs before they are absorbed, except in the case of those inorganic substances which are given for their direct effect on the gastric mucous membrane. The practitioner gives other drugs, for the most part, without considering how far they may be altered before they leave the alimentary canal. He is guided by what is known of their subsequent action on the system and of their effect in disease, and he is no doubt thus guided, in the main, correctly. Nevertheless, the subject is not an unimportant one, since the influence of the digestive ferments on drugs must, or rather should, determine the time of their administration in relation to the process of digestion. At present, careful attention is paid to this point in choosing the time at which to administer those therapeutic agents which are designed to have a direct action on the stomach, but, as regards others, it is not considered, except in so far as it influences the rapidity of their absorption. No facts, indeed, have hitherto been available for the guidance of the practitioner on this important subject. It is only since the processes for artificial digestion have been perfected that it has become possible to ascertain such facts, and the subject is certainly worthy of the attention of the pharmacological experimentalist.

These remarks are suggested by a series of experiments of this nature, although with a different object, which were described at the recent meeting of the Pharmaceutical Conference by Mr. George Brownen. This gentleman has endeavored to ascertain to what extent the digestive ferments may be made available for the production of preparations of various drugs. The question necessarily involved that of the extent to which their active principles suffered in the process. The constituents of rhubarb were found to be extracted, with remarkable completeness, by treating an infusion first with an acid preparation of pepsin, and then, after neutralization, with an alkaline solution of pancreatin. The former extracted 47 per cent. of the rhubarb, and the latter 13 per cent. more, leaving only a residue of cellulose and earthy salts. Infusion of calumba, prepared with boiling water, and passed through a similar process of digestion, gave somewhat similar results; only spongy cellulose, associated with a trace of berberia, was left. Cinchona and opium, on the other hand, behaved differently; the gummy and extractive matters were dissolved and retained in solution, but a considerable quantity of the alkaloids was left behind. About half the cinchona and two-thirds of the opium were dissolved. The cinchona tannin was destroyed in the process of digestion, and failed to precipitate gelatine. The arabin of gum acacia remained apparently unaffected by the process, but a peptonizing change was wrought upon some other constituent of gum, possibly a nitrogenous impurity. The mucilages obtained from Irish and Iceland moss were also tested, since they hold an intermediate position between foods and medicines. The alkaline extract of the pancreas seemed to exert very little action on Irish moss, although the proteolytic ferment of the pancreas, extracted with acids, soon destroyed the viscidity of the mucilage, and divided the jelly into soluble and insoluble portions. Iceland moss behaved somewhat differently. A jelly of it became flocculent when acted on by the gastric ferment, and under the influence of pancreatic extract deposited yellowish white flakes, consisting of non-crystalline masses, possibly peptic acid.

Of more direct interest, however, is the action of the digestive ferments upon definite organic compounds. The acidulated extract of the gastric juice decomposed a watery solution of salicin very slowly and imperfectly, but the pancreatic ferment split up the salicin into saligenin and glucose. Jalapin remained intact after digestion with the pepsin solution, but pancreatic digestion withdrew from it a copper-reducing substance. Neither process had any influence upon santonin. A solution of tannin, treated with the acid pepsin solution, became turbid, but the turbidity disappeared after the addition of a little more hydrochloric acid, and prolonged digestion seemed to have no further influence. The pancreatic extract, however, quickly rendered tannic acid incapable of precipitating gelatine, as it had been found to do in the experiments with cinchona bark, apparently by converting it into gallic acid. The experiments of Mr. Brownen go no further, but he has evidently opened a field of considerable importance, in which other observations will probably yield results of considerable practical value to physicians as well as to pharmacists.—*Lancet*, Sept. 23, 1882.

Iodoform in Purulent Ophthalmia.—Mr. W. J. Milles, Senior House Surgeon at Moorfield, reports (*Royal London Ophthalmic Hospital Reports*, August, 1882) that he has employed this drug for some time past in purulent affections of the conjunctiva and cornea, and he believes that, in suitable cases, it is of very great service.

The best method of using it is either in a very fine powder, when care should be taken that it is ground down very thoroughly; or in the form of ointment of variable strength, the usual form being gr. xxx to ʒj of vaseline, the stronger form to ʒj to ℥j. The importance of iodoform in ophthalmic practice is that it produces less pain and irritation than any other antiseptic that he is acquainted with; that it can be used in a concentrated form; and that it volatilizes very slowly.

Eighteen months ago he gave it in an extended trial in ophthalmia neonatorum, and came to the opinion that it was only useful when one could treat the disease from the commencement (within the first two or three days). In the later stages, when there were thickening of the lids and a granular condition of the conjunctiva, he found that its effects in stopping the purulent discharge were very slight. He was more pleased with iodoform in the treatment of gonorrhœal ophthalmia, possibly from the fact that the patients suffering from this affection were more immediately under control. The treatment was combined with the use of boracic acid lotion, or a solution of perchloride of mercury (gr. i to ℥j), and, of course, a constant application of iced compresses. In a number of cases the acuteness of the swelling and the profuse discharge rapidly diminished, and the cornea was saved under this form of treatment.

Having seen the rapidity with which an indolent ulcer of the leg changes its character under the use of iodoform, he was led to try its effect on the slowly spreading infiltrated ulcer of the cornea. It quite answered his expectations. In several cases (though other treatment had been tried without effect), with the constant application of iodoform, the ulcers ceased to spread, the infiltration of their edges rapidly disappeared, and a rapid recovery ensued.

Excision of Primary Syphilitic Induration.—Dr. Tomaschewsky, writing of an investigation which he had conducted in Prof. Tarnowsky's clinic (*Petersb. Med. Woch.*, September 9) to ascertain what effect incision of primary syphilitic induration exerts upon the appearance and course of secondary symptoms, states as the result of trials made in fifty-eight cases in which excision was performed at the tenth to the fourteenth day of the disease, that these were nowise influenced,

the course of the disease continuing just as if no excision had been made.—*Med. Times and Gaz.*, September 23, 1882.

THE MODIFICATIONS IN THE CALIBRE OF BLOOD-VESSELS IN AMPUTATED LIMBS.—From a careful examination of the calibre of the bloodvessels in stumps, M. SEGOND has found:

1. That after amputation the calibre of arteries and veins of the limb subjected to operation nearly always decreases. This is even observed when the amputated portion represents, as in the case of amputation of the hand or foot, only a small portion of the limb.

2. The extent of this diminution in calibre is not limited to the stump itself, but exists in the entirety of the mutilated member.

3. The reduction in calibre can not be attributed to atrophy of the limb, as it occurs before the limb undergoes atrophy.

4. The primitive reduction in calibre of the vessels is probably an active cause in the production of atrophy in limbs of which a portion has been amputated.—*Revue de Chirurgie*, September, 1882.

THE SUTURE OF DIVIDED FLEXOR TENDONS OF THE HAND.—DR. JOHN CHAMBERS reports two cases of division of flexor tendons of the hand. One was left to nature and resulted in a disabled finger; the other was sutured and a cure was obtained. He gives the following directions as to details in operating:

1. Before using the knife, pass a fine director into the sheath as a guide to the incisions; otherwise there will be difficulty in finding it, as it is in a collapsed state from retraction of the tendon. The sheath must be slightly incised at the proximal and distal ends to allow of sufficient exposure of the tendon to pass the suture.

2. Use a fine needle with a large eye, entering it a quarter of an inch from the ends of the tendon, which should be merely approximated. If the ends are drawn closely together, the tension may cause the tendon to split.

3. Catgut, well carbolized, as made in Edinburgh, is preferable to other material for sutures. The ends should be cut off short.

4. Strict antisepticism is desirable to secure the best results. While suppuration occured in the case reported, it was, he thinks, owing to the fact that in closing the external wound free drainage was not sufficiently provided for. As a result, the secretion from the irritated synovial sheath was free, giving rise to tension, exciting inflammation, and marring the normal reparative process. It is essential to the success of the antiseptic method in all operations, that drainage be well attended to.

5. Keep the finger or thumb, as the case may be, moderately flexed, with the hand secured to a well-padded splint by a lightly applied bandage.

6. Commence passive motion as soon as the external wound is healed.—*Indiana Med. Journ.*, Sept. 1882.

THE NATURE OF RIGOR MORTIS.—The question of the cause of the different kinds of rigor in the muscle has been discussed anew, this time by MISS SCHIPILOFF (*Centr. f. d. med. Wiss.*, 1882, p. 291). She sought an analogy between the changes of myosin in salt solutions and those of the myosin in the muscle. Particularly interesting are the comparisons between the *rigor mortis* and the *rigor caloris*. Myosin, which is precipitated from its solutions by acids and by a small quantity of distilled water, retains its chemical character, and does not change into syntonin nor into the insoluble modification; hence fresh muscles and those which have become spontaneously rigid must contain the same amount of myosin (if its changes cause rigor), which is found by experiment to be true. Again, myosin is precipitated from its solutions by heat, but the body thus obtained is no longer myosin, and is completely insoluble in NH_4Cl, hence the *rigor caloris* must be totally different from the normal spontaneous *rigor mortis*. "The *rigor mortis* depends upon a temporary precipitation of chemically unaltered myosin from its semi-liquid condition in the muscle plasma; this precipitation is caused by the post-mortal development of acidity, whose further increase brings about a resolution of the rigor in muscular tissues which have not yet become putrefied."—*Boston Med. and Surg. Journ.*, September 28, 1882.

MUSCULAR ATROPHY FOLLOWING INJURY TO JOINTS.—A patient (male, aged twenty-three) came under M. CHARCOT'S observation with the following history: A year before, he had sustained a slight injury to his right knee by falling, but had walked for some distance directly afterwards. A trifling swelling of the joint supervened, and lasted for a few days; but the loss of power in that leg was quite out of proportion to the apparent amount of joint-trouble, and did not improve when this latter quite passed off. When he came to the hospital a year later the thigh was obviously wasted in front; the quadriceps femoris did not respond to the induced current, nor to a strong constant current. It was clear, therefore, that there was no "degenerative" atrophy such as occurs in infantile paralysis (when a muscle does not respond to a strong induced current, but responds unduly to a weak constant current, it is said to exhibit the "degenerative" reaction). It should be noted, however, that the rectus femoris and vastus internus (the vastus externus had shown some reaction to the other forms of electricity) responded to the influence of static electricity, and that a blow on the rectus femoris was followed by contraction. The knee phenomenon was present, and excessive on both sides. There was no ankle-clonus on either side. M. Charcot lays great stress upon two points: 1. There is no necessary relation between the intensity of the articular lesion, and that of the paralytic and atrophic phenomena. 2. In cases of this kind it is the extensor muscles which suffer almost, if not quite, exclusively. The following is the mode by which M. Charcot would seek to explain these cases: "The joint-lesion has, by means of the irritated articular nerves, reacted on the spinal centre, aad there it modifies the centres whence the motor nerves, and the nerves which regulate the nutrition of the muscles, arise. There must exist in the spinal cord a more or less direct relation between the cells belonging to the articular centripetal nerves, and those of the motor and atrophic nerves of the extensors, since the result is always constant, viz., that on them, or mostly so, the atrophy falls. . . . No other theory satisfies the conditions so well; and we are reduced to admit a secondary spinal affection, in consequence of which the paralysis and atrophy are set up. . . . But what is this modification of the spinal centre? It is not a profound modification of the cells of the anterior cornua, that would be an infantile paralysis. We must, then, have to deal only with a sort of inertia, with a stupor of the cell element." To explain the exaggerated knee phenomena, he supposes that there is a morbid state of exaggerated reflex excitation in the whole extent of the spinal cord outside the area which he has already assumed to be in a state of torpor. M. Charcot would explain in the same way the paralysis and atrophy which are found in chronic articular affections, *e. g.*, chronic rheumatism. He notes that in these cases also the extensors are especially liable to be affected, and that the so-called "tendon reflexes" are in excess.—*Med. Times and Gaz.*, September 23, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,

SATURDAY, OCTOBER 14, 1882.

THE PHYSICAL EDUCATION OF FEMALE COLLEGE-STUDENTS.

A FEW days since, there fell under our eyes a circular issued by the "Association of Collegiate Alumnæ," on the subject of Physical Education in Colleges for Women.

In spite of the presumed editorial omniscience, we must plead previous ignorance of the very existence of such an association. It is a "Yankee notion," very evidently, for, though graduated from eight different colleges, east and west, eight of the nine officers reside in or near Boston. Nine colleges are represented in the association, viz.: Vassar, Wellesley, Smith, Oberlin, Cornell, Michigan, Wisconsin, Wesleyan, and Boston. If the association does as good work in other directions as is done in the little four-page pamphlet before us, it has an unchallenged right to exist. A table is first presented, showing the status of physical education in these nine colleges. Lectures on physiology are given in all but Wellesley—an omission which the authorities there should promptly remedy. Only three have lectures on hygiene, an error equally grave, especially when the teacher of physiology could so readily combine the teaching of hygiene with that of its handmaid. All have gymnasia except Michigan and Boston. Vassar, Smith, and Wellesley alone have calisthenics. Not one has any athletic sports proper, or athletic associations, or any definite course of physical education. Vassar and Wellesley alone require one hour of physical exercise daily, and Wellesley alone requires a certain standard of health for admission.

On the basis of these facts, the association in a few plain, forcible, and practical paragraphs, urges certain suggestions upon the parents, the college authorities, and the college students. Parents are cautioned against errors in the pre-collegiate days of their daughters, as to social life, sleep, food, clothing, exercise, etc. College authorities are urged to provide systematic courses for physical training, with requirements as to a standard of health, before entering college, and as to exercise during the college course; to establish lectureships on physiology, hygiene, heredity, gymnastics, sanitation, etc.; and to remedy existing defects in ventilation, and other sanitary requirements in college buildings. The students are urged to take proper care of their health, and the means thereto are briefly indicated. The association hopes to publish a series of short practical monographs on suitable subjects, at some future time.

If the plans of the Association are realized to any great extent, the boys will have to look to their laurels, lest the girls outstrip them in health, and possibly in some of their athletic acquirements.

It is a capital work which the Association has begun. Besides the nine colleges composing it, there are a number of other colleges for women, and all over the land a host of private and public schools, which will profit by any substantial progress they may make. We hear much ado about the deterioration of the race in physical vigor. Happily, however, there is a counter-current very strongly developed, too, among our educated classes towards a more positive bodily health. It has been asserted again and again that girls cannot pursue a thorough college course, and yet enter womanhood physically fitted for the burdens of life, especially those of the mother and the housekeeper. Dr. Clarke, Dr. Goodell, and many another have pointed to "Vassar Victims," as examples of what ruin such an education will work. Yet spite of it all women's colleges are multiplying, and men's colleges are opening their doors to women; and not a few instructors say that women can and do work as well as men, and when they work wisely, that it is done with as little danger to health. Arguments and facts are bandied to and fro without any as yet very definite conclusion.

It is of the greatest importance for us as a people to know definitely the facts in the case—not the isolated uncoördinated facts as to this girl or that, or even this college or that, but *all* the facts, from as large an area of country, and as large a number of colleges, and as large a number of women as possible. Women's colleges have now been established long enough, if not for a definite, at least for an approximate estimate of their effects on the health of their students. Accordingly, we beg leave to suggest to this admirable Association, that

no subject could better receive their earnest attention and research than the establishment of the facts in the vexed question. To do this would require considerable time and labor, but the result would be worth it all. The later histories of each graduate should be obtained, as to race, age, health, marriage, the number and health of their children, their occupations, if in ill-health, its nature and supposed cause, if deceased, the cause of death, with numerous other points which will readily suggest themselves. All this should be examined, and reported upon with an honesty above suspicion. If the future mothers of our country are being ruined physically by our methods of education, who should wish with such downright earnestness of purpose, to remedy the impending evil as our educated women themselves? If a false cry is being raised which will hamper the just and wholesome intellectual development of women, who are more interested in showing it than the graduates of our women's colleges? Truth, broad truth is what we should seek. Individual experience is apt to be very erroneous; only large numbers eliminate errors. But until facts based on such numbers are forthcoming, each of us must use his own or his neighbor's personal experience as the best, and indeed the only guide.

We present these views to the Association, as suggested by their excellent circular, and trust they will act promptly, and with an unbiased desire for truth in obtaining and publishing the results of an extended examination after the method we have indicated.

VULPIAN'S EXPERIENCE WITH ANTISEPTICS IN TYPHOID.

In his service at the Hôtel-Dieu, Vulpian has made some comparative observations on the utility of the various antiseptics employed in typhoid fever. Iodoform has not given any good results. This is the more remarkable, since this agent now occupies an important place as a remedy in septic processes. Salicylate of bismuth is an excellent antiseptic, but it is not readily soluble, and hence the large dose necessary to obtain any result—from two to three drachms daily—presents many inconveniences. It is found, also, to increase the tendency to nasal and intestinal hemorrhage. Boracic acid, carried up to the dose of three drachms daily, by regular increment of the daily dose, has not done any good. The best results have been achieved with salicylic acid. Vulpian has administered this in doses of three or four grains every half-hour until the daily quantity has reached the large proportion of three drachms. In some patients, especially in young men, he has produced some cerebral disturbance—a light delirium—in others albuminuria has appeared; but this is by no means an uncommon symptom in typhoid when left to its own course, and in some cases the albuminuria disappears when as much as 200 grains of salicylic acid are taken daily. The real cerebral effect which may, then, be referred to salicylic acid, is a slight delirium. Under the salicylic-acid treatment the temperature falls in forty-eight hours, three to four degrees; and this reduction of the body-heat is more persistent than that effected by carbolic acid. At the same time there ensues a notable amelioration of the general condition of the patient. But Vulpian does not pretend that the mortality from the disease, nor its duration, is notably diminished by the modification in its symptoms thus effected by salicylic acid.

In the course of the discussion on Vulpian's observations, it appears that the central idea of the antiseptic treatment of typhoid is to act on the typhoid germs introduced into the intestinal canal from without. Vulpian gives the preference to salicylic acid because it possesses so little toxic activity *per se*. He objects to the use of the carbolate of sodium for this purpose, because, owing to its solubility, it cannot be accumulated in the blood in sufficient quantity to act on the disease germs. The treatment by purgation during the period of invasion—the prodromal stage—was also considered. One of the modes of the "specific treatment" of typhoid, as pursued by our German colleagues, is the mercurial plan, which consists in the administration of purgative doses (ten grains) of calomel during the first week. Several doses of this kind must act in three ways: sufficient bichloride is produced to act on the typhoid germs as a poison; the germs are removed by the purgative action; the temperature is lowered by the combined result of these actions. The range of temperature has a certain relation to the number and activity of the germs present in the blood. Hence their destruction at an early period becomes very desirable.

THE ACTION OF HELENINE ON THE BACILLUS OF TUBERCULOSIS.

Still another item has been added to our long list of scientific debts to our trans-Atlantic *confrères*. While yet laden with our burden of gratitude to Koch for his alleged discovery, we learn that we are not less indebted to France. Germany, we are told, has discovered the nature of tuberculosis; France must discover its antidote. M. de Korab has saved the credit of France in this scientific rivalry.

At a recent meeting of the Académie des Sciences, M. Bouley read a note by M. de Korab, in which he detailed the results of some experiments made with helenine as an antidote to the effects of the bacillus tuberculosis. He was led to undertake

this study from the good results observed in cases of diseases of the respiratory apparatus in which helenine had been administered.

In the first place he found that this drug hindered the development of the bacilli in culture fluids, and he also claims that the administration of helenine will prevent the symptoms of tuberculosis in animals inoculated with the bacillus. Thus he reports four series of experiments: in the first series he inoculated seven guinea-pigs with the bacillus obtained from serous culture-fluids; a fatal result occurred in all; three guinea-pigs were then injected with the bacilli of the culture-fluid to which helenine had been added; no tubercular lesions appeared.

In his second series, tubercular sputa treated in the same way were substituted for the cultivated bacilli, and the same result was produced; the sputum treated with helenine was innocuous.

His third series of experiments was made on ten rabbits, into whose peritoneal cavity serum containing bacilli was injected; five of these animals received three centigrammes regularly of helenine, and showed no evidence of tuberculosis, while the five others died on the eighth to tenth day.

In this fourth series the bacilli were injected into the anterior chamber of the eye in four rabbits, and the characteristic results appeared on the tenth day; two of the rabbits received regularly two centigrammes of helenine every day; they recovered, while the two other rabbits died.

We fear that the desire to sustain the national reputation for scientific research has led M. de Korab to take a rather too enthusiastic view of the specific properties of helenine; his results are wonderfully successful, but to carry conviction as to their reliability they require the confirmatory observations of other investigators.

HYPODERMATIC INJECTIONS OF STRYCHNIA IN NERVOUS AFFECTIONS.

Dr. Cerenville strongly advises the subcutaneous injection of strychnia in chronic myelitis, when the morbid process is arrested, and in those examples of posterior spinal sclerosis characterized by trivial aggravations of the symptoms, in incontinence of urine, and in cerebral affections.

There is no danger in this mode of administering strychnia, provided the treatment is begun by small doses gradually increased. In some subjects an abnormal excitability to the action of strychnia is observed. Such cases indicate an irritative action already existing at the site of the lesion. This excitability may have diagnostic importance. If the reaction following the introduction of strychnia is excessive, or if it is excited by minute doses, it may be rightly assumed that the local morbid process is in an active state. The converse is equally true. The cumulative action of strychnia may be confounded with an abnormal excitability of the part the seat of disease. This, however, is possible only when the medicament is administered in the form of pills. When thus administered a slow accumulation may take place; but when given hypodermatically at proper intervals, the absorption and elimination of this agent occur promptly, and accumulation does not take place.

In the treatment of posterior spinal sclerosis, whilst the action of the medicament administered by the stomach was practically *nil*, when given subcutaneously the incoördination of muscular movement was lessened, and the incontinence of urine ceased altogether. When the amount of strychnia injected subcutaneously is excessive, the intolerance of patients is manifested in various ways: in one it is an excessive irritability, or at another time a temporary trismus; in another, an obstinate headache; in some, jerkings of the muscles of the neck and extremities; in others there is vesical tenesmus. The quantity of strychnia necessary to excite these phenomena will vary greatly in different subjects, according to their susceptibility, and to the state of the centric lesions.

THE LAST DITCH.

The *Medical Record*, consistently with its general advocacy of the New York Code, "can hardly believe" that the County societies seriously intended to instruct their delegates how to vote at the next meeting of the State Medical Association, and thinks that unless each delegate exercises his right to "free thought, free speech, free opinion, and free voting," a just and impartial decision can never be reached on any question. It is led into this painful state of doubt by a letter from a well-known physician who, for his part, does believe that the County societies have instructed their delegates for 1883 to vote for reversing the action of the meeting of 1882, but thinks it "a grave mistake." They agree, however, in the opinion that the particular subject to which these remarks refer—which, as has been said, was the New York Code—requires further and fair discussion and a presentation of the "different pros and cons."

We are neither so cautiously incredulous as the *Record*, nor so dissatisfied with the situation as its correspondent. Indeed we are reckless enough to feel absolutely certain that about eight-ninths of the County societies in the State of New York which have taken action on it, did deliberately, unequivocally, and almost unanimously direct their delegates to vote against the so-called "new code," at the coming February meeting of the State Medical Society, and they did it, knowing full well the exact signification and effect of their action. We

believe that when they described it as "opposed to public interests, and dishonoring a noble profession," or as "impolitic, unwise, and hurtful," or in other even more derogatory terms, they knew and meant exactly what they said, and we think, moreover, that nothing they have ever done has more clearly shown their sound common sense and high standard of professional honor.

As to the *right* of the County societies to instruct delegates in reference to their votes and influence upon any topic of general interest, it is puerile to question it. The County societies form the basis of representation in the larger association; the delegates receive from them the necessary credentials, and have always been expected to express upon all such matters the previously known sentiment of the society, and not their individual opinions. They have, at the time of receiving their appointment and instructions, ample opportunity to protest or to resign; and if they felt their condition to be one of "moral and intellectual servitude," or that their office was "humiliating," and their position "unenviable and undignified,"—to employ the touching language of the *Record's* correspondent—they would probably express themselves to that effect. It may be added also that there is every chance for fair discussion, and even for the advancement of "pros and cons," in the County societies themselves, and that when they "utterly repudiate," "protest against," "strenuously object to," and otherwise strongly disown any special theory or rule of conduct, the presumption is that they do so only after full and careful consideration, which could hardly be improved upon even by the presence of "five of the best known medical men of the State of New York," who, if we may again quote the *Record's* correspondent, deliberated upon the subject for a year, and finally recommended the new Code. The mountain and the mouse does not begin to afford a parallel. Perhaps a closer one could be found in the history of certain other wise men of Gotham whose enterprise also came to grief. This statistical attempt to work upon the feelings of the delegates, and to imbue them with the idea, first, that the societies have no right to instruct them, and next, that if they have, it is unmanly to be instructed, may be characterized in one word by an expressive Americanism—Buncombe!

MEDICAL BRAVERY.

THE engagement at Kassassin, in the recent Anglo-Egyptian war, afforded two illustrations of the bravery of the army medical officers, which are worthy of being recorded, especially, as in the English army the surgeons are classed as "non-combatants," and are persistently denied their proper rank and recognition.

The only officer who was killed on this occasion was Surgeon-Major George Shaw, who, for the purpose of rendering assistance to a wounded man, voluntarily exposed himself to a scathing fire from the enemy. He was struck in the temple by a rifle-bullet, which penetrated and lodged in the brain, and lived only about three hours in an unconscious state. During the same engagement some movement of the troops left the first company of the Army Hospital Corps in an isolated and dangerous position. The medical officer in charge refused to permit the work of dressing the wounded, many of whom needed instant attention, to be intermitted for a moment, and declined to make any change of position until that duty had been attended to. His men, some forty in number, accordingly filled their haversacks with sand, so as to form temporary breast-works, took the rifles of the wounded who were unable to use them, and defended their charge until the arrival of the cavalry terminated the enemy's attack.

These facts are obtained not from the columns of the London daily press, nor from the illustrated weeklies, which are filled with descriptions and representations of the heroism of the Household Cavalry and the valor of the troops in general, but from modest notices in the correspondence of one or two medical journals. So far as we have seen, the lay press has had no word of commendation for the men who, relegated officially to an inferior social and military position, without the stimulus of the tremendous excitement of the officers who make or mar the game of war, and with little or no prospect of sharing the honors in the event of success, thus coolly and unflinchingly risk and lose their lives in the performance of their duty, not only upon the field of battle, but in confronting and combating disease in its manifold shapes. We have no wish to detract from those soldiers who have so well acquitted themselves during the recent campaign, but truly brave men can afford to give honor wherever and to whomsoever it is due. We should been glad to see some mention of the medical department in the despatches or some allusion to it in the encomiums upon the army with which the English press is now filled.

EXPLOSIVE COMBINATIONS.

ATTENTION has been repeatedly called to those extemporaneous combinations which form explosive mixtures. It may be useful to our readers to point out some of those most frequently prescribed. Amongst these are chlorate of potassa, permanganate of potassa, chromic acid, and glycerine.

A pomade composed of chloride of lime, sulphur, and other substances, will detonate when rubbed up in a mortar, and the whole mass may deflagrate.

When the hypophosphite of lime or soda is triturated alone, if pure, it may explode. Pills composed of the oxide of silver, are apt to decompose in a tremendous explosion. When the tincture of iodine is mixed with ammonia, the iodide of nitrogen—a violently explosive substance—is formed. If this is triturated in the presence of water, an explosion is almost certain to occur. A mixture of chlorate of potassa and tannin is apt to explode. The dentifrice containing chlorate of potash and catechu, has been known to explode in the mouth, when rubbed with a dry brush.

REVIEWS.

THE PHYSICIAN HIMSELF, AND WHAT HE SHOULD ADD TO THE STRICTLY SCIENTIFIC. By DR. D. W. CATHELL. Pp. 194.

Also 2d edition, pp. 208. Baltimore: Cushings & Bailey, 1882.

"THE proper study of mankind is man!" It was an ingenious idea of Dr. Cathell to put into writing the traditional and personal experiences of medical men, in respect of their business and technical relations to the world about them. There is nothing which men so much enjoy as the contemplation of themselves and their affairs—nothing which they read with so much zest as the account of their own doings and sayings, and the formal expression of their thoughts and experiences. Dr. Cathell has rendered them this great service; he presents to physicians who have succeeded the interesting details of their daily work, and he points out the road to success for the benefit of those about to start on a professional career.

There is much in "The Physician Himself" to commend—some things which should be condemned. Some of the methods set forth in the book have been unpleasantly exemplified in the means used to promote its sale. The circular containing extracts from private commendatory letters and reviews, sent forth under the signature of Dr. Cathell, to urge the sale of the work, is not a delicate proceeding, to use no harsher term. We must object to precepts, similar in their design to this example, which we find in the book. Thus, on page 11, it is stated—"It is proper and advisable to display your library, microscope, and other aids to precision; also your diploma, certificates of society membership, pictures of eminent professional friends, etc." Again on page 18, "If, at your office and elsewhere, you make use of instruments of precision—the stethoscope, ophthalmoscope, laryngoscope, the clinical thermometer, magnifying glass, microscope, urinary analysis, etc., they will not only assist you in diagnosis, etc., but will also aid you greatly in curing people by heightening their confidence in you, and enlisting their coöperation!" In such injunctions, the spirit of humbug is inculcated. The real use of the instruments of precision is the shadow, whilst the substance is the impression which such an appearance of scientific skill will make on the people. It is as much as to say to young practitioners, surround yourselves with much brass paraphernalia, to impress your clients, and, if you can, use them in diagnosis also, but above all, impress them. This is the spirit of the advice. Externals, a right appearance before the public, and the exhibition of mere paraphernalia, are the proper objects of a physician's attention. It is true here and there, right doing as well as correct conduct are urged on the physician, but the tendency of the instruction is to encourage pretension, rather than the possession of genuine merit. Whilst the book thus tends to encourage the cultivation of mere externals as a means of introduction to successful practice, it is by no means wanting in the expression of the noblest sentiments. The moral reflections, however, seem to be of the Joseph Surface character; intended rather to make an impression on the bystanders, than to affect the inner life and conduct.

Notwithstanding the unpleasant effect which the work makes on the whole for artificiality, for mechanical morality, and for mannerisms that are contrived to excite interest in their possessor merely, it is a distinctively useful and, in some respects, original work. No young medical man can fail to be benefited by its perusal, and no established practitioner can read it without obtaining useful hints for his guidance. Indeed, we believe, so perfect is the model of a young physician there drawn, that no man can form himself on it and fail to succeed. No experienced physician can rise from the perusal of the work, without a feeling of profound respect for the acuteness, the sagacity, and the knowledge of human nature possessed by its author. Although such a work encourages attention to mere externals, it must, on the whole, improve the professional status of those who conform to its instructions.

In the second edition which we have just received, some changes have been made in the expressions used, typographical errors have been eliminated, and the matter has been, in some places rearranged; but on the whole, the work stands as it originally appeared. Our final judgment, formed after the perusal of both editions, is, that "The Physician Himself" is a work of very great merit, barring the superficial and mechanical morality which it inculcates, that its author must be a shrewd and successful physician, who joins to great regard for external forms, a genuine love of his professional duties, and who is, at the same time, a shrewd observer of the weakness of mankind and skilful in his adaptation of the means necessary to utilize them for his own advancement. We can, however, conscientiously commend the work to our readers, with the conviction that no man can conform to its dicta, without having a measure of success. At the same time, we must insist that merit so conspicuous does not need the aid of *clap-trap* to obtain a proper recognition. No physician possessed of such capacity as shown by Dr. Cathell, could fail to rise in his profession; but our admiration of the ability unconsciously displayed in the book, is saddened by the reflection that such superior capacity had not found an adequate space for its proper development in the higher walks of professional activity.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 5, 1882.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

AFTER the reading of the minutes of the previous meeting and various reports, the scientific work of the evening was taken up. This consisted in a paper by DR. EDWARD G. JANEWAY, entitled

CASES ILLUSTRATING THE DIAGNOSIS AND LOCALIZATION OF BRAIN DISEASES, AND THEIR DIFFICULTIES.

By way of introduction, Dr. Janeway said he had first intended to confine himself to the subject of locali-

zation, but upon reference to what had already been done in this direction, he found that the cases bearing upon this point had been so thoroughly examined by Pitres, Grasset, Charcot, Ferrier, Deboyer, Nothnagel, and Exner, that he believed the time could be more advantageously occupied in another way.

He preferred, first, to speak of the difficulties of diagnosis between certain brain troubles and general diseases, and afterwards to present cases illustrating the subject of localization.

Dr. Janeway first took up the consideration of the difficulties presented by typhus fever in distinguishing it from cerebral diseases. He made special mention of cases coming under his observation which had been mistaken for meningitis and cerebritis.

The disease which was most likely to mislead between both of these, because of its implicating the brain, was what has only been recently recognized as coming in the category of special diseases, viz., acute endocarditis. He alluded to the fact that embolism in the brain, petechiæ on the surface, and fever would naturally mislead one in differentiating between typhus and brain diseases. The diagnosis would, in a given case, mainly depend on finding petechiæ on the surface, associated with paralysis or aphasia, indicative of embolism in the cerebral arteries. Naturally, in such a case, one would suspect ulcerative endocarditis. An illustrative case was adduced.

Typhoid fever was next taken up, which was less liable than typhus to be mistaken for brain disease, but still, once in a while, errors did occur. Embarrassment in diagnosis was mainly due to the symptoms of stiffness at the back of the neck and marked cerebral manifestations.

The reader of the paper then took up malarial fevers. He spoke of the fact that nervous diseases, with periodicity, were more apt to be mistaken for malarial trouble than the latter for nervous diseases, and instanced particularly examples of tumors with periodic headache, abscess, and pachymeningitis, secondary to bone disease, as ostitis media, injury to bones of head, etc. Congestive malarial troubles, with coma and convulsions, might very easily be mistaken for brain disease. He stated that in two cases he had found the lesions of cerebro-spinal meningitis together with pigmentation of the spleen and liver, and one case in which there was pigmentation in the vessels of the brain, showing that combinations might occur. The hypodermic syringe had been used in two cases for the purpose of determining whether satisfactory diagnostic results could be obtained by exploring the spleen. The spleens were swollen, and though a drop of blood was obtained, no evidences of pigmentation were found by its examination. Mention was made of cases in which the muscular pain was out of all proportion to the cutaneous hyperæsthesia, and in which an exploration of the pectoral muscles was made for trichina, in order to avoid error in diagnosis, or to determine a coincidence.

The difficulties in differential diagnosis presented by pleurisy and pneumonia were spoken of, particularly when occurring in children. Pneumonia was the more apt to be mistaken for brain trouble, especially when it began in the centre of the lung, or high up in the axilla, or posteriorly — places rarely examined in children. The symptoms of stiffness in the back of the neck and delirium present at the onset of the disease, were the principal causes of failure in diagnosis.

Bright's disease was liable to mislead in a good many ways, among which were the following: First, it had been laid down as a rule of diagnosis, that albumen and casts in the urine were good distinctive signs between coma of Bright's disease and hemorrhage in the brain. This statement, Dr. Janeway thought, should be taken with a great deal of reserve. In such cases he depended more upon the nature of Bright's disease; whether it was the small contracted type of kidney, with arterial changes and hypertrophy of the left ventricle. In its detection a paralysis, monoplegia, or hemiplegia was of a great deal more value than albumen and casts, because albumen was found in the urine in cases of hemorrhage. This point was illustrated by citing the case of a sixteen-year-old boy, who had as symptoms, headache, muscular soreness, hyperæsthesia of the skin, choked disk, fever, marked stiffness of the back of the neck, delirium, unconsciousness — symptoms which seemed to indicate involvement of the brain. The post-mortem showed small kidneys, hypertrophy of the left ventricle of the heart, and hemorrhage into the middle ventricles of the brain, due to rupture of a small miliary aneurism in the tænia semicircularis.

A case was next mentioned showing the liability to a severe mistake. The patient was a young man who had been examined by an oculist and had been told that he was suffering from retinitis due to Bright's disease. Over thirty examinations of urine failed to show the first symptoms of Bright's disease. The patient had brain symptoms and suffered from great muscular weakness. These lasted for some time, then improvement took place, and he finally recovered with blindness.

The author of the paper now passed to cases illustrative of localization.

The first example cited was that of a patient having aphasia and agraphia, but with no paralysis anywhere. The only history attainable from the man was by gestures, which were perfectly intelligible. He had received an injury to the left side of the head at a point just about opposite the position of the third frontal convolution, as a result of a premature blast.

A second example was that of a man who had been hit with a billiard cue in the left temporal region. The symptoms were aphasia, agraphia, and paralysis of the right side of the face and the right side of the tongue, but no arm or leg paralysis. The patient recovered.

Next came a case of tumor of the brain, situated for the most part in the upper portion of the two central convolutions and paracentral lobule, the symptoms being hemiplegia on the opposite side, involving the arm and leg.

A fourth example was that of a woman having a tumor pressing on the temporo-sphenoidal lobe. There was no paralysis. She died as the result of falling out of a window in a drunken brawl.

Other cases were omitted on account of multiple lesion and previous publication. One patient had pachymeningitis with lesion of the sixth and ninth nerves, and paralysis of the tongue and external rectus. The autopsy showed compression of the above nerves at their exit through the dura mater by the dura mater. This case was alluded to because the statement was found in some books that such a condition of things never occurred.

A case of paralysis of the lower part of the face, that part usually considered indicative of cerebral paralysis, was then alluded to, in which the autopsy showed a gliomatous tumor of the pons. Other paralyses were present in this case, which made the diagnosis possible during life.

Dr. Seguin opened the discussion by saying that the paper had been a very instructive one to him, especially the first part of it, which set forth the difficulties in the differential diagnosis of brain diseases from general diseases. He thought specialists were not generally well versed in this part of the subject. Certainly his own experience had not been much. He thought that in many cases where there was a coexistence of cerebral and renal degenerative symptoms, it was im-

possible to avoid a double diagnosis of miliary aneurism and kidney disease.

Prof. John C. Dalton being called upon by the Chair, remarked that he thought such papers as that of Dr. Janeway, that tell us something of the difficulties of this matter, are a little more what we want than the recitation of cases which point out the coincidence between the loss or disturbance of particular functions, and an injury or destruction of certain parts of the brain. Cases of the latter kind are satisfactory and entertaining in a great many ways, but when he recalled the great anticipations which were felt when the doctrine of cerebral localization was first inaugurated, and the remarkable corroborations that followed by experimental physiologists who found that by irritation of particular parts of the brain, particular paralyses followed, it seemed as if a new era began, and that all we had to do was to map out the brain, as the old phrenologist had mapped it out for another purpose. Though he thought these anticipations were just, new difficulties were beginning to present themselves. He presumed that every pathologist present knew of instances of lesions of particular parts which were not accompanied with the symptoms attributed to such lesions; and also where the symptoms were present, but were not accompanied by destruction of those particular regions of the brain.

Now, he did not imagine there was any contradiction between physiology and pathology; there are only difficulties. And at the present stage these difficult cases and apparently contradictory cases are the ones we want to discuss. We are all familiar with Hitzig's cases, in which, by the application of an electrode to particular parts, he always produced definite muscular movements upon the opposite side of the body, and afterwards, when he cut out these parts of the brain, paralysis followed. These observations were supported by pathological evidence; but after a while we found that it was not all clear.

The first difficulty was that extraordinary one disclosed by experimentation, in which it was found, after cutting out the motor tract and producing muscular paralysis upon the opposite side of the body, that it was not a permanent paralysis. The animal was hemiplegic the next morning after the operation, but in two weeks he had recovered the lost power. Now, how can we explain this? A good many different explanations have been offered. First of all, we may suppose that other parts of the brain take up the functions previously performed by that part of the cortex which has been removed. This explanation, Prof. Dalton did not think was satisfactory. It was too clumsy. According to this theory, after cutting away portions of the brain controlling the movements of certain parts, other cells in the neighborhood, that have never before been called upon to act in the capacity of those removed, gradually take up their function, and after a time perform it regularly.

Regarding the recovery of sensibility, it was stated that, after the removal of the angular convolution, the animal was at first blind, but afterward recovered sight. One of the most ingenious explanations of this fact was that of Monk, who says that, after cutting out the angular convolution the animal is not blind; that he sees as well as ever, but does not know what he sees. The animal is soul blind, as Monk terms it. According to this author, if an adult man who had always been blind could suddenly be enabled to see his best friend, he would not know him. Monk supposes that the visual image is upon the eye, but to know what that visual image means is another thing. Experience gradually teaches him what this image is. According to Monk, this is what happens when the angular convolution is cut away. The animal sees as well as before the operation, but does not know what he sees. Monk thinks that in the neighborhood there are other cells capable of doing the work of those which have been removed, but have never been called upon to do so. These cells have got to go through the same process as the others did from the beginning, just as if the animal was born again. This was a very ingenious theory, but he thought all would agree that it was rather deep water. Take a dog and do such an operation upon the right side, when you hold a piece of meat before the left eye the dog does not bite at it. He appears not to see it. Prof. Dalton thought that in an animal naturally as curious as a dog, he would make some attempt to examine the piece of meat if he saw it, even if he did not know what it was.

Prof. Dalton discussed the paper still further. He was followed by Drs. W. R. Birdsall and Hermann Knapp, and the discussion was closed by Dr. Janeway.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, October 4, 1882.

W. S. W. Ruschenberger, M.D., President, in the Chair.

Dr. H. Augustus Wilson reported a case of

TRANSPOSITION OF THE VISCERA,

the comparatively rare occurrence of which, he considered a sufficient excuse for occupying the time of the College. He regretted that he was not able to offer a more complete record of the case; but a careful dissection was impossible without taking an unwarranted risk of septic poisoning, as the abdominal cavity was filled with fetid pus.

Frank M., aged 21, died at the Presbyterian Hospital of purulent peritonitis. I shall ignore in this paper the pathological conditions found at the post-mortem examination, inasmuch as they have no bearing upon the subject under consideration.

The patient had been aware since boyhood that his heart was misplaced, and upon one occasion a physician told him that that was the reason he was left-handed. He had never been very strong; but it does not appear that he ever had any serious affection the cause of which could be assigned to his misplaced viscera.

In 1878, when he first came to the hospital, Dr. James Markoe, under whose care he was, noticed that not only was his heart perceptible in the fifth interspace of the right side, but also by percussion ascertained that this organ occupied the same relative position upon the right side that it should upon the left. He found, also, that the liver and spleen were transposed, but no further changes seem to have been noticed.

At the time Dr. Wilson made the post-mortem examination, he found externally nothing to indicate the great changes in the positions of the internal organs, except that the right testicle was suspended at a lower level than the left. When he had opened the thorax and abdomen, and laid bare the organs contained therein, the appearance to him was as though he was looking at the body reflected in a mirror. It was like the photographer's negative.

The *heart* first attracted his attention, and was found to be normal in every respect, but occupying, as already noted, a position upon the right side. It looked as though it had been pushed over to its present position without changing materially its relations with other organs. The right side was the pulmonary side and the left the systemic side, and in this respect the organ performed its functions in a normal manner. The aorta, starting from the left ventricle, followed a somewhat irregular course, crossing over the right bronchus

and going from there to the right side of the vertebral column, along which it descended upon the right side. The branches given off from the arch of the aorta were the two coronary arteries unchanged, the innominate going up the left side of the neck and giving off the left common carotid and left subclavian, while coming from the right portion of the arch were the right common carotid and right subclavian.

The *lungs* were reversed. The right lung was found to be smaller to allow space for the heart. It had two lobes. The left lung corresponded in appearace to what is commonly the right lung, was shorter than its fellow, being pressed up by the liver, was broader, and had three lobes.

In the *abdominal cavity* the liver occupied the left hypochondriac and partly the epigastric regions, the large lobe to the left and the smaller ones to the right, the gall-bladder and everything else similarly changed.

The *stomach and intestines* were transposed. The stomach was partly in the right hypochondrium and partly in the epigastric region. The pylorus extended forward and downward toward the middle of the abdomen. The spleen was on the right side, and attached to the greater curvature of the stomach.

The *cæcum* was situated in the left iliac fossa, and the colon ascended on the left side and crossed from left to right side of the abdomen. From there it descended and terminated in the sigmoid flexure upon the right side.

As already stated, the man was naturally left-handed. Hyrtl was the first to advance the theory that we are normally right-handed because of the more direct flow of blood to the brain upon the left side. And this theory would be substantiated if all cases where the heart and great vessels were transposed were left-handed; but such is not the case. A few years ago a theory was advanced that right-handedness depended upon natural selection. But the easiest explanation is that from earliest infancy we are instructed to use the right hand always in preference to the left. When a person with transposition of the viscera is left-handed we may call it a coincidence. In any other view, it would be extremely difficult to account for the far larger number of persons whose organs are arranged normally and yet are left-handed. In the cases that are noted in the journals Dr. Wilson has not been able to find statistics enough to draw any inferences, for, when this condition is noted, right-handedness appears to be as frequently met with as left-handedness in cases where the viscera are transposed.

Peacock, in his monograph on Malformations of the Heart (T. Peacock, *Malformations of the Heart*, 2d edit., 1866), says that the most common of all the internal displacements is that in which the heart is placed upon the right side in a position corresponding to that which it should occupy upon the left, and that this displacement is almost always associated with more or less complete transposition of other viscera. Occasionally the heart is transposed, while the other organs are unchanged (Sur l'Ectopie de l'appareil de la circulation et particulièrement sur celle du cœur.—*Rep. Gen. d'Anat. et de Phys. Pathol.*, t. ii., 1826, p. 1).

Among the earliest recorded cases are those of Servius and Schenkius in Rome in 1643 (Thomas Bartholinus, *Hist. Anat. Cent.*, ii. 29. Amst., 1654), and one by Riolan in 1652 (Allen Thompson, *Glasgow Med. Journ.*, vol. i., 1853, p. 220).

The first case recorded in which the malformation was noticed during life appears to be that described by Morand (Méry, *Memoirs of Academy of Paris for* 1866) in 1666. This case seems to have attracted considerable attention at the time, and was said to have suggested to Molière the transposition of the heart and liver which he puts into the mouth of Sganarelle in his play of *Mèdecin Malgré lui*, published about the time this case was reported.

In cases of more or less complete transposition, the arteries, if they do not retain their natural positions, may be displaced in almost all conceivable ways.

Dr. Gamage (*N. Eng. Journ. Med. and Surg.*, iv., 1815, p. 244) reported a case in which the aorta arose from the right ventricle and the pulmonary arteries from the left ventricle. Mr. Abernethy (*Philosophic Trans.*, 1793, p. 59) saw a child, ten months old, where the portal veins terminated in the vena cava, the liver being supplied from an unusually large hepatic artery. Mr. Douglas Fox (*Lond. Med. and Phys. Journ.*, vol. ii., 1824, p. 474) reported the result of a post-mortem examination in a case where the heart was transposed, and the aorta, after crossing the right bronchus, passed behind the lower end of the trachea, over the vertebral column, and pursued its usual course from there down the left of the spine.

For a very complete account of a case similar to the one now reported, and for an exhaustive study of the histology of such malformations, the reader is referred to Dr. Allen Thompson's paper in the *Glasgow Medical Journal.*

As regards the practical application of this case, it would be well to bear such abnormality in mind as a possible condition in cases brought to a physician's notice in an unconscious condition. It will readily be seen that considerable difficulty might arise is forming a diagnosis. In surgical operations upon the thorax or abdomen it would prove a serious complication, as, for instance, in colotomy, paracentesis abdominis or pericardii.

TRANSACTIONS OF THE OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, October 5, 1882.

Vice-President, T. M. Drysdale, M.D., in the Chair.

Dr. W. Goodell exhibited the specimens and gave the histories of the following cases:

NEPHRECTOMY FOR RENAL CYST.

Mrs. C. M. G., aged 52, and married for twenty-eight years, has had three children, the youngest of whom is twenty-five years old. For many years she has had pain in the left renal region, and sharp attacks of gravel. This pain was so increased by jolting that she was unable to drive even in a carriage with double springs; but she has never experienced the excruciating pain of a stone passing down the ureter; of this she is positive. Four years ago she began to enlarge, but she did not suspect a tumor. As her health grew worse, she came on from the west and in last July consulted Dr. J. F. Bird about it. He recognized a cyst and called Dr. Goodell in to see her. Despite her age, her catamenia were not only regular, but too free. Dr. G. expected to find a fibroid, but the womb measured only three inches, and it was also very movable and wholly independent of a large cyst, which filled up the abdomen like an eight months' fœtus. The lower edge of the cyst could be felt per vaginam lying in front of the womb. Percussion elicited all the phenomena peculiar to ovarian cysts. Coronal resonance was marked. There was dulness in front showing the complete absence of intestines from that region—their presence being alleged to be one of the most trustworthy signs of a renal cyst. As the lady stated positively that there were changes in the size of the tumor, Dr. G. was disposed to regard it more as a cyst of the broad ligament than one of the ovary.

The operation was performed on September 16th. As soon as the cyst was reached, it was ascertained

that it was not ovarian or parovarian; but it was fully fifteen minutes before its true character was discovered. The cyst was covered with a very vascular but loose layer of peritoneum, to which in the lateral regions the intestines were attached, and in which they seemed to be imbedded. This was cut open and stripped off from the whole cyst, which now revealed on its lower border an expanded and healthy portion of the left kidney. To confirm the diagnosis, a small calculus was found within the cyst, and a much distended ureter discovered. The pedicle formed by this process of enucleation consisted, below the ligature with which it was secured, of the renal bloodvessels enveloped in connective tissue. But to get a button of tissue sufficient to prevent all slipping of the ligature, the operator was obliged to leave on its distal side a small portion of the cyst, but none of healthy kidney.

It was evidently a case of hydronephrosis, but the uterine sound was passed into the ureter and no obstacle was met with; it probably did not reach the bladder. This ureter was brought out at the lower angle of the wound, and secured there by one of the sutures. Nineteen days have now elapsed since the operation, and the lady has done uniformly well, and sat up to-day for the first time.

HYDATID OF MORGAGNI.

The lady from whom this specimen was taken was operated on by Dr. Goodell on September 4th, and promptly recovered. The cyst was of the left ovary, but the right one being also diseased, was removed. Attached to one of the fimbriæ of the oviduct is a very beautiful specimen of a hydatid of Morgagni. This little body, so often found attached to the ovary, was of interest because those small cysts of the abdomen which, after attaining a small size, would burst and usually refill, were, in Dr. Goodell's opinion, cysts of this hydatid.

CYST OF THE PAROVARIUM.

This specimen was taken from a young woman, aged 22. The tumor was first noticed eight years ago. Dr. Goodell aspirated her before the clinic at the University of Pennsylvania, in October, 1880, and November, 1881. On each occasion a perfectly limpid fluid was removed, and the diagnosis was consequently made of cyst of the broad ligament. As the cyst again refilled, she demanded its removal, and she was accordingly operated on before a ward-class on September 19th. The cyst sprang from the left side, and had the usual delicate and vascular wall. Spread out on its lower border, is the corresponding ovary, which could be very readily overlooked by a careless observer. The right ovary, being much enlarged and filled with small cysts, was also extirpated. When first removed, it contained fine corpus luteum, but the alcohol had dissolved this out, leaving merely the deep pit which held it. The operation was performed just two weeks after her last monthly period. The usual metrostaxis occurred on the fifth day after the operation. The patient is convalescing well.

PAPILLOMATOUS UTERINE GROWTHS.

Dr. W. H. Parish exhibited two vials, containing apparently similar growths removed from the endometri of two patients, one of which from concurrent symptoms, he considered benign, but the other he thought malignant. In the first case, menstruation had ceased for a year, after which it had returned and became constant and profuse. She had suffered from prolapse following labor, twelve or fifteen years ago. Dr. Parish dilated the uterus with two sets of spongetents, after which he introduced his finger and found a number of elevations as large as a pea; some of these he removed by means of curettes, and others by seizing them by forceps and twisting them off. Some metritis followed the operation, but no blood has been lost in the last four weeks.

The second specimen was removed from a carcinomatous uterus, by means of the curette and the ecraseur.

Dr. Goodell remarked that he did not allow the revelations of the microscope to govern him in his treatment of bleeding uteri. He had under his care, recently, three such cases, all of which were reported by noted microscopists to be carcinomatous, but one of these cases was entirely cured by local measures.

One case of lacerated cervix with ectropium and free hemorhage, which was pronounced undoubtedly cancerous by a microscopist of high repute, was relieved by scraping and cured by operation. Another case pronounced cylindrical epithelioma, by the same gentleman, recovered after operation.

A patient of Dr. C., while in this city, was referred to me for examination as to the cause of persistent menorrhagia. Ether was given, and a careful and thorough examination made, and the round and sharp curettes were used; but Dr. Goodell could find no cause except a few minute granulations. This class of cases is usually found among stout or plethoric women, and the hemorrhage will recur after any treatment, although temporary benefit can be obtained. When the curette is passed over the walls of the uterus, it exercises a tonic effect, and a contraction results checking the hemorrhage.

Dr. A. H. Smith has had under treatment a number of cases of marked anteflexion, generally in young girls, in whom dysmenorrhœa is followed by very profuse menorrhagia, which proves very exhausting, and will not yield to internal remedies. Examination shows no recognizable cause, but a stem pessary will secure entire relief in a few months. He has seen six such cases within the last three years. He has had under treatment cases resembling epithelioma of the uterus, in which the introduction of a large sponge tent has resulted in complete cure, and secured the cessation of profuse and hitherto uncontrollable hemorrhage.

Dr. Parish: Some cases of incurable hemorrhage are due to inflammatory adhesions of the uterus to surrounding tissues, which will disturb the circulation and modify nerve action. He considers the smooth-wire curette a valable aid in diagnosticating the condition of the endometrium, as its passage over the uterine wall will distinguish between healthy and unhealthy uterine tissue. A patient suffering from uterine hemorrhage for three weeks following a possible miscarriage at three months, was cured by one application of the smooth curette, which brought away some granular matter.

CORRESPONDENCE.

MAGGOTS IN THE NARES.

To the Editor of The Medical News.

Dear Sir: It fell to my lot to see a case of no little rarity, and of which I desire to make a brief report.

Mr. K., of Alexander, Ill., has been for some years afflicted with a catarrh which has never received any attention and which has become an ozœna. He is an industrious Irish farmer against whom the main complaint that can be made is that he "takes an occasional drop at a dance or the like, for the sake of his constitution."

After the last dance, which continued until morning, under the stupefying effects of the alcohol, he lay in the grass until near noon. A considerate blue-bottle, which wished to deposit her eggs in a safe place, chose

the fetid secretions of the man's nose, and effectually discharged the contents of her oviduct. The environment being favorable to their development, in due time sixty-five healthy *maggots* began to inspect their new and novel quarters, and seem to have passed a favorable opinion on the nares and post-pharyngeal space, for they could not be induced to leave it through kind treatment or harsh, and, in spite of irrigation, they grew and prospered, except a few, less skilful than the rest, which, falling from the turbinated heights, lost foothold, and, once outside the nostril, found it impossible to return, and met with a summary destruction. A large number survived a week and eluded the attempts of the vigilance committee (of two neighboring physicians).

The case began to assume dangerous symptoms—erysipelas of the face was an unwelcome visitor. Between maggots and œdema of the nose and soft palate no air could be made to pass, and the mouth was the only respiratory avenue. This is the condition in which I found him when called in consultation on the morning of Sept. 22d, eight days after the dance—and to me no description could be an exaggeration of the appearance of the nauseating spectacle seen under the condensed illumination of the rhinoscope, the nostril being distended by a speculum.

They resisted the action of water completely, and it was found necessary to stand guard with forceps and catch each one until the last of the family were in captivity. Considerable surfaces of bone were found denuded, but so faithful had the operations of these little workers been that no particle of odor was to be distinguished.

Respectfully,

A. E. PRINCE.

JACKSONVILLE, ILL., Sept. 22, 1882.

NEWS ITEMS.

THE PROGRESS OF YELLOW FEVER.—The news from *Pensacola* during the past week is exceedingly meagre, consisting only of the figures indicating the number of cases taken sick daily, and the deaths which have occurred. They are as follows, reported up to and including October 2d, 875 cases and 87 deaths:

Dates.	Cases.	Deaths.
October 3d,	55	5
" 4th,	56	3
" 5th,	54	4
" 6th,	71	4
" 7th,	64	2
" 8th,	77	4
" 9th,	48	5
Total to date,	1300	114

Brownsville, Texas.—But two despatches have been received from Brownsville by the Surgeon-General of the Marine-Hospital Service during the past week, the yellow fever having almost disappeared in that section. Only twelve cases and two deaths are reported up to and including the 7th of October, 1882, making a total, during the epidemic, of 1912 cases and 109 deaths.

The disease is now limited to a few mild cases inside the Arroyo Cordon, but is reported to continue with great severity in the Mexican towns and ranches bordering on the Rio Grande river; the infected districts are prevented from spreading the disease in Texas by an efficient cordon, extending from Brownsville to Laredo.

Pensacola, Fla.—Official reports, by mail, from Pensacola, have been received by the Surgeon-General of the Marine-Hospital Service to include the 4th of October, 1882, as follows:

Dates.	Cases.	Deaths.
September 30th,	44	3
October 1st,	45	4
" 2d,	45	5
" 3d,	55	5
" 4th,	55	5
Total,	244	22
Previously reported,	725	76
Total during epidemic,	969	98

The origin of the epidemic is involved in obscurity. Many cases were rumored before the presence of the disease was announced by the Board of Health on August 29th. That the disease on board the Galeta, which was sent to sea on the tenth of that month, was yellow fever appears to be conceded, but the history of that vessel, showing a period of forty days of health between her departure from an infected port and her fever while at Pensacola would indicate that she became infected there rather than that she introduced the poison. There are many who believe that fever prevailed in the port and among the shipping before the arrival of the Galeta. The city medical men have had their time fully occupied in attending to their patients. No doubt when all is over the local authorities will institute an investigation into the origin and spread of the disease, but in a case of this kind the delay of a few weeks or even days increases the difficulties in the path of the investigator. Some who could have given important information die, others sail from the port and their testimony is lost. We understand that Major G. T. Walthall, of Mobile, Ala., is engaged on behalf of the National Board of Health in prosecuting an inquiry into the circumstances attending the introduction of the disease. Major Walthall is an earnest worker in sanitary matters, a member of the American Public Health Association, and well fitted by education and experience to take up this line of inquiry. It is probable that some light will soon be thrown on this matter.

CHOLERA.—In Yokohoma and vicinity there occurred during the first twelve days of September, 283 new cases of cholera and 223 deaths, making a total since the epidemic began (in last April) of 3,509 cases and 2,223 deaths. All the new cases are among the native population.

Cholera has prevailed, also, for months past, in many of the East Indian Islands, and in some of the ports of British India. From Bombay, at the end of August, it was brought to the shores of the Red Sea by a vessel, the "Hesperia," which was sent to quarantine at Camaran, where the Imperial Ottoman Sanitary Administration has a large establishment, with hospitals for the sick, and quarters for those who are under observation. Strict orders have been issued to enforce the quarantine laws against all vessels from the East. It is probable that if cholera were introduced into Egypt in the present disorganized condition of that country, the disease would spread rapidly, and be a source of danger not only to Europe, but to this country. The shores of the Red Sea are far from us, except by telegraph; yet at present the manner in which the quarantine is there enforced has a great and practical interest for the whole of this country. Early in September, quarantine was established in Malta against vessels coming from the East. Perhaps we may soon have to learn by a bitter experience how we have erred in leaving our ports unguarded against the intrusion of this Eastern pestilence.

SMALLPOX IN ILLINOIS.—The Quarterly Report of the Secretary of the Illinois State Board of Health

states that at the date of the last report, June 30th, there had been a total of 190 cities, towns, and villages in which smallpox had appeared since Nov. 1, 1881, of which number twenty-two had occurred in the preceding quarter, and there were still cases remaining at nine points. Since then there have been cases at Paxton, in Ford County, near Prairie du Rocher, in Randolph County, and on an island in the Mississippi river opposite Harrisonville, Monroe County. The disease has also been reintroduced into Jersey County through a suit of second-hand clothes bought in St. Louis.

The Paxton cases originated with a stock-dealer and importer of horses, who contracted the disease en route from France in the stock boat Friga, on board of which was a mild case of varioloid. The boat, it is said, escaped inspection at quarantine in New York, and as Hefner, the importer, did not travel on an immigrant train in this country, he also escaped the inspection service. The disease was confined to Hefner's house, but his wife, son, and daughter were attacked, and the son died.

The Monroe and Randolph County cases are believed to have originated from an infected mattress, supposed to have been thrown into the river and washed ashore on Staton's Island. Owing to failure of prompt recognition of the disease, a hired man who had been exposed, was allowed to go to Randolph County, near Prairie du Rocher, where together with himself, there have been in all nine cases with five deaths. The disease seems to have been of a very mild type on Staton's Island, no deaths occurring out of the ten cases.

It is worth while calling attention, in this connection, to the markedly different results obtained in counties under township organization and in those where, in the absence of Town Boards, the County Commissioners are charged with the duties of health authorities. While of course, the most efficient work is done and the disease is most promptly "stamped out" in localities where there are regularly organized Boards of Health, it is yet true that, as a rule, the Town Boards have been only less efficient, and the disease has been generally promptly mastered by their efforts, On the other hand, in counties where the County Commissioners alone have charge, there has, as a rule, been delay in action or neglect, resulting in a spread of the contagion beyond the first cases or families and an undue prolongation of the disease. In Alexander County, for example, the first cases near Commercial Point occurred in the latter part of April and the contagion was not finally eradicated until the 20th of July. The recent outbreak and spread in Monroe and Randolph counties are, to some extent, due to similar causes.

At this date there is one remaining case near Prairie du Rocher, and three in the hospital in Chicago. Aside from these there are no new cases known to exist in the State at present.

The decline of the epidemic in Chicago since the inauguration of the Immigrant-Inspection Service is clearly shown in the following table:

MONTH.	Cases Reported.	Deaths.	REMARKS.
April	321	95	Inspection began June 1.
May	281	65	Average decline before inspection, 12 per cent.
June	154	29	
July	44	11	Average decline since inspection, 78 per cent.
August	24	5	
September	7	3	

The New York Code.—The Broome, Franklin, and the Columbia are the latest of the New York County Medical Societies to repudiate the new code, and to instruct their delegates accordingly.

By order of the Medical Society of the County of Kings, the discussion of the New York Code will take place at the stated meeting to be held on Tuesday, October 17th.

The Franklin County (N. Y.) Medical Society at its quarterly meeting recently held, adopted the following resolutions:

Resolved, That the Franklin County Medical Society deplore the act of the State Medical Society abolishing the wise Code of Medical Ethics by which it had for so many years been governed, and substituting therefor an unwise and senseless code—a code which sacrifices the self-respect and honor of members of a once honorable profession, in order to pander to the self-interest of a few specialists in New York and other large cities of the State.

Resolved, That our delegate to the State Society be instructed, should opportunity present, to vote for the repeal of the present code, and for the readoption and restoration of the old code.

Resignation of Dr. Oliver Wendell Holmes.—It is rumored that Dr. Oliver Wendell Holmes is about to resign his Professorship of Anatomy in the Harvard Medical School.

Journal Changes.—The *Louisville Medical News* announces that hereafter it will be under the management of Drs. Lunsford P. Yandell and L. S. McMurtry, of Louisville. Both of these gentlemen are widely and favorably known to the profession, and possess the talent and culture to worthily fill the editorial chair of the lamented Cowling.

The *Sanitarian* announces that on the first of next year it will appear as a weekly journal, with thirty-two double-column quarto pages. It will continue under the editorial management of Dr. A. N. Bell.

Medical Education in the United States.—The Annual Report of the Commissioner of Education, for the year 1880, has just been issued by the Government, and from it we learn that during the last decade the number of medical institutions, and of medical students in the United States has about doubled, and that the number of instructors has nearly trebled.

The number of "regular" schools is put down at 72, with 1,131 instructors, and 9,876 students. The "Eclectic" schools number 6, with 65 instructors, and 833 students. The "Homœopathic" schools number 12, with 188 instructors, and 1,220 students.

Pathological Prize.—The Pathological Society of Philadelphia, will award the sum of twenty-five dollars, or a gold medal, for the best pathological report, with or without specimens, read before April 1, 1883, by any member of the Society, who at the time of presentation, holds the position of hospital resident.

Personal.—Dr. Morell Mackenzie, of London, has been making a six weeks' tour in this country. His travels have extended across the Continent, and he has received marked attention.

Dr. J. J. Woodward, of the U. S. Army, has returned from Europe, and the profession will regret to learn that his health has not been improved by his trip.

American Public Health Association.—The tenth annual meeting of the American Public Health Association will be held in Indianapolis, under the Presidency of Prof. R. C. Kedzie, on October 17 to 20.

A SPECIAL SESSION OF THE SANITARY COUNCIL OF THE MISSISSIPPI VALLEY will be held during the meeting of the American Public Health Association at Indianapolis, Ind., October 17–20, at such time as may be found most convenient, with reference to the programme of the Association. Of this due notice will be given by announcement, at an early hour after the Association has convened. Questions of importance, affecting the sanitary interests of the Mississippi Valley, will be considered.

SUCCESSOR TO PROF. FRIEDREICH.—PROF. ERB, of Leipzig, is mentioned as the successor of the late Prof. Friedreich, of Heidelberg.

OBITUARY RECORD.—We have just learned from our foreign exchanges of the sudden death of DR. HILLAIRET, one of the most distinguished practitioners in Paris. He died of angina pectoris, in his consultation room; he was 67 years of age, and was engaged in the publication of a treatise on "Diseases of the Skin," of which the first fasciculus appeared last year.

A GERMAN AMBULANCE ASSOCIATION.—A society similar to the English Ambulance Association has been formed in Berlin. It was founded at the suggestion of Prof. Esmarch, and its purpose is to render aid to the wounded in cases of accident as rapidly as possible. The Empress has accepted the position of patroness.

ALUM AS A FIRE EXTINGUISHER.—M. DUMAS, the eminent chemist, has been trying some experiments with a concentrated solution of alum, the results of which he lately communicated to the Academy of Sciences. He proposes this substance as an extinguisher of fires, as it renders non-inflammable all substances with which it is placed in contact. He recommends its use for putting out fires in streets, etc. One of the members present observed that in theory the idea was plausible enough, but that its execution would be simply impracticable, owing to the enormous quantities of alum that would be required to meet the demand. It was, however, suggested that several articles in theatres, private houses, shops, etc., might be rendered non-inflammable by having them saturated in a solution of alum, and thus reduce to a minimum the risk of spreading fires.—*Lancet*, Sept. 16, 1882.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending September 30, 1882, indicate that bronchitis has considerably increased, that puerperal fever, scarlet fever, whooping-cough, and membranous croup have increased, and that dysentery has decreased in area of prevalence.

Compared with the average of reports for the months of September, in the preceding five years, all diseases except puerperal fever, and cerebro-spinal meningitis, were less widely prevalent during September, 1882, than has been usual during September; and only bronchitis and puerperal fever were noticeably more widely prevalent during the week ending September 30, 1882, than has been usual.

Including reports by regular observers and by others, diphtheria was reported present during the week ending September 30, and since at 23 places, scarlet fever at 10 places, and measles at 4 places. A case of smallpox was reported at Grand Rapids, October 3.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 2 TO OCTOBER 9, 1882.

WOODWARD, J. J., *Major and Surgeon.*—Leave of absence extended four months on account of sickness.—*S. O. 233, A. G. O., October* 6, 1882.

WILLIAMS, JOHN W., *Major and Surgeon.*—Now on leave of absence, to proceed to San Francisco, Cal., and report in person to the Commanding General Division of the Pacific, for duty in Department of the Columbia.—*S. O. 228, A. G. O., September* 30, 1882.

WATERS, WM. E., *Major and Surgeon.*—To report in person to the Commanding General Department of the East, for assignment to duty.—*S. O. 228, A. G. O., September* 30, 1882.

IRWIN, B. J. D., *Major and Surgeon.*—On being relieved as attending surgeon headquarters Military Division of the Missouri, to proceed to Whipple Barracks, Arizona, and report in person for duty as Medical Director, headquarters Department of Arizona.—*S. O. 228, A. G. O., September* 30, 1882.

FORWOOD, WM. H., *Major and Surgeon.*—Relieved from duty in Department of the Platte, and to report in person to the Commanding General, Military Division of the Missouri, for duty as attending surgeon at those headquarters.—*S. O. 228, A. G. O., September* 30, 1882.

SMITH, ANDREW K., *Major and Surgeon.*—Relieved from duty in Department of Arizona, and, on expiration of present sick leave, to report by letter to the Surgeon General.—*S. O. 228, A. G. O., September* 30, 1882.

EWEN, CLARENCE, *Assistant Surgeon.*—Relieved from duty at Fort Elliott, Texas, to proceed to Fort Gibson, Indian Territory, and report to the Commanding Officer at that post for duty.—*S. O. 198, Department of the Missouri, October* 3, 1882.

BURTON, H. G., *Captain and Assistant Surgeon.*—Granted leave of absence for four months.—*S. O. 229, October* 2, 1882.

PURRILLE, HENRY S., *Captain and Assistant Surgeon.*—To be relieved from duty in Department of the East, and to report in person to the Commanding General, Department of the Platte, for assignment to duty.—*S. O. 228, A. G. O., September* 30, 1882.

MOSELEY, E. B., *Captain and Assistant Surgeon.*—To report in person to the Commanding General, Department of the East, for assignment to duty.—*S. O. 282, A. G. O., September* 30, 1882.

SKINNER, JOHN O., *Captain and Assistant Surgeon.*—To be relieved from duty in Department of Arizona, and to report in person to the Surgeon General.—*S. O. 228, A. G. O., September* 30, 1882.

LORING, LEONARD Y., *Captain and Assistant Surgeon.*—To be relieved from duty in the Department of the Missouri, and to report in person to the Commanding General, Department of the East, for assignment to duty.—*S. O. 228, A. G. O., September* 30, 1882.

MCCREERY, GEORGE, *Assistant Surgeon.*—To report in person to the Superintendent Mounted Recruiting Service, Jefferson Barracks, Missouri, to conduct a detachment of recruits to the Department of Arizona. On completion of that duty, to rejoin his station in that Department.—*S. O. 233, A. G. O., October* 6, 1882.

WAKEMAN, W. J., *First Lieutenant and Assistant Surgeon.*—Upon being relieved at Fort Douglas, Utah Territory, to proceed to Fort Fred Steele, Wyoming Territory, and report to the Commanding Officer at that post for duty, in the absence of Assistant Surgeon D. G. Caldwell, on leave of absence.—*S. O. 106, Department of the Plate, Oct.* 6, 1882.

BIRMINGHAM, H. P., *Assistant Surgeon.*—To proceed to Fort Bayard, New Mexico, when relieved at Fort Elliott, Texas, and report to the Commanding Officer for duty.—*S. O. 198, Department of the Missouri, October* 3, 1882.

WATERS, W. E., *Surgeon.*—Ordered to Madison Barracks, New York, for duty as Post Surgeon.—*S. O. 178, Department of the East, October* 5, 1882.

OWEN, WM. O., JR.—*First Lieutenant and Assistant Surgeon.*—To proceed to Fort Townsend, Wyoming Territory, and report to the Commanding Officer for temporary duty at that post.—*S. O. 138, Department Columbia, September* 22, 1882.

CALDWELL, D. G., *Captain and Assistant Surgeon.*—Granted leave of absence for one month, with permission to apply for an extension of three months.—*S. O. 105, Department of the Platte, October* 3, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

DIPHTHERIA.

A Lecture delivered by Invitation at the Bellevue Hospital Medical College, New York, Oct. 12, 1882.

BY MORELL MACKENZIE, M.D. LOND., M.R.C.P.

SENIOR PHYSICIAN TO THE HOSPITAL FOR DISEASES OF THE CHEST AND THROAT, LECTURER ON DISEASES OF THE THROAT AT THE LONDON HOSPITAL MEDICAL COLLEGE, ETC.

GENTLEMEN: When I found that Dr. Bosworth had been kind enough to invite me to lecture to you, I need not say I felt very grateful to him, but I hesitated to accept the great honor, on the ground, first of all, because I object to all lectures; and, secondly, on account of the vastness and difficulty of the subject he had chosen for me to speak upon.

I think the days for teaching by means of lectures are passed. Lectures did very well in the middle ages, when medical books were more scarce than they are now, and perhaps are still very good for clinical purposes. They may also be useful where it is desired to show the use of instruments, or demonstrate special modes of investigation, as, for instance, in experimental physiology. One reason why they are still so largely in vogue is on account of lecturing being a traditional mode of teaching. Then, too, it is supposed to be a means of reaching that class of students who will not read or study from books, but I believe that class does not exist in America, for my observations have led me to the conclusion that American medical students are industrious and never shirk hard work. Therefore, I feel that the days for didactic lecturing in this country are altogether ended.

The subject chosen for me to speak upon was not selected by myself, and I feel that it is impossible to do anything like justice to it in a comparatively few minutes. However, I will not take up your time with any further excuses, but will proceed at once to make running commentaries upon the disease in question.

I will not trouble you with an historical account of diphtheria, beginning with Hippocrates and running down to the present time, as is so customary for medical authors when treating of various diseases. The ancient medical writers had such a convenient vagueness of expression that now when an author is writing upon a given disease, even though it be one so recently recognized as pernicious anæmia, he has only to consult Hippocrates to find a description which he can easily apply to it as proof of the disease having existed from the earliest times. I will simply tell you, and that, perhaps, will be of interest to you, that Dr. Samuel Bard, an American physician, was the first to write an accurate and comprehensive description of diphtheria. Previous to this, as some of you may know, a very accurate description of croup was written by Dr. Hume and several other English writers, but all these took a local view of the disease. They did not understand the nature and various manifestations of the disease. It was Dr. Samuel Bard who first accurately described it and pointed out that what were supposed to be different diseases were in part only different manifestations of one affection, diphtheria.

Nor will I endeavor to give you a minute definition of the disease, for it is very difficult to give a good definition of anything. If you attempt to define life, man, etc., nothing is more difficult, and the same is true of diphtheria. If you try to give a concise definition, you are sure to omit something of importance. I myself tried to give a comprehensive definition of diphtheria in a book which I wrote a few years since, and thought I had succeeded pretty well. But my reviewers said it was a description, not a definition. Since then I have made no further attempt in this direction.

The disease in question is sometimes considered to be a specific inflammatory condition of the mucous membrane of the throat; being produced by a definite cause. It generally occurs epidemically, though sometimes endemically. It is characterized by the formation in the throat of a false membrane. These are its main features. Now we have to consider what is the specific nature of the disease. Is it the result of certain germs or not? One of your most distinguished American physicians, Dr. Jacobi, does not believe in the germ theory of diphtheria; at least that was his belief two years ago when he wrote upon this subject. You are well aware that certain minute bodies called micrococci are found in the membrane of diphtheria. These are supposed by some to be the cause of diphtheria, while others believe there is nothing specific about them as they are found under other conditions.

When I wrote my book three or four years ago I was rather guarded on this point. I said there was a good deal to be said on both sides of this question; that if these germs did not cause the disease, they had a good deal to do with it. And I consider the question is not yet settled as to whether or not bacteria are the cause of the disease. You are probably aware of the recent experiments of Dr. Wood, of Philadelphia, which have shown that bacteria are exceedingly abundant in the false membrane of the severer forms of diphtheria; that, in fact, their number is in direct proportion to the virulence of the disease; and that they are present in all cases. He demonstrated that these germs actually attacked the white corpuscles of the blood, thus killing the blood, as it were, at its very fountain head. My opinion is, that these bacteria have a most important connection with the disease. Dr. Wood says also that bacteria are present in almost every inflammation of the throat. But the important point which he has drawn attention to is that they are found in numbers corresponding to the severity of the attack. He showed also that their contact with healthy mucous membrane reproduced the disease. When the bacteria became dried up and were no longer active, they were not capable of reproducing the disease. But it may be argued in good faith that the drying process also destroys the specific poison of the disease as well as the bacteria. Therefore I say we are still where we were four years ago; the subject is still *sub judice*. It is of all things, important that you should not lose sight of this question, because, if germs have nothing to do with the disease, you might be led to think it is less infectious than it really is.

This brings us to the point, whether croup is really a separate disease. Now, I hold that croup and diphtheria are quite identical, and that it will not be long before we shall have exhaustive works upon diphtheria which will consider it and croup as identical diseases. One reason why there is so much confusion about this matter, is that the meaning of the word croup is vague, it having been applied to a variety of conditions. There is what is called diphtheritic croup, catarrhal croup, and nervous croup. I think a term that can be

applied so loosely is a very unsatisfactory one to use in medicine. I consider croup with membrane in the throat to be the same as diphtheria. Then there is, as I have just said, catarrhal croup and laryngismus stridulus or nervous croup. I would strongly recommend to give up the term croup altogether, for it is used so vaguely that it only confuses. I believe though, after all, it is merely a theoretical question, and will not materially affect our practice, for we do not treat disease according to names. We look at a patient and observe the character of the attack from which he is suffering, determine the conditions of the pulse, and if he be strong or feeble. We do not treat the patient according to whether the disease is called by this or that name, but according to the indications present in his particular case. The discussion as to the identity or non-identity of croup and diphtheria reminds one of that which was seriously discussed many ages ago, viz. as to how many angels could sit together on the point of a needle, and is perhaps, after all, of little more importance.

We now pass on to that which is of much greater importance, the prognosis. I shall leave out altogether the symptoms and pathology of the disease, for if I were to go into a description of the various forms of diphtheria, it would consume three or four hours. All these matters are thoroughly considered in the text-books. I want to urge upon you not to be guided in your prognosis by statistics. You must consider your patient quite independently of all statistics. The figures published by some authors indicate that half of the patients die, while those of another may indicate that more than half recover. According to our present systems of gathering statistics we can only accurately determine the number of fatal cases, for we have no means of knowing whether all those that are reported as having recovered were really cases of diphtheria. I have known of some gentlemen to have reported treating two hundred cases of diphtheria without a death. But I have always thought that all of these could not have been cases of true diphtheria, or else the physician was exceedingly fortunate in having a large number of very mild cases. When the disease is accompanied by a thick membrane in the throat, especially in the larynx, it is very fatal. Therefore let your prognosis be most guarded.

A point I wish to speak of is, a high temperature early in the disease. This, I believe, to be indicative of a serious case. In diphtheria the temperature is usually not much elevated, but in the severer cases, it is often excessively high from the beginning, and is accompanied with great depression. The case is likely to prove very serious if there is sickness at the stomach, and especially if there be vomiting.

As some of you may know, I consider the disease to originate from germs; that it is from the commencement a local disease. I am in fact of the same faith, regarding this matter as your townsman Dr. Elsberg, who more than ten years ago pointed out the fact that the disease was in almost all cases primarily local. Sometimes the severity of the attack may from the beginning be so great, that the disease will appear to be constitutional from the commencement.

These cases I believe are analogous to those of scarlet fever, where the patient is stricken down from the very moment of onset of the disease. These points bear upon the prognosis.

Now we pass to the treatment, which is perhaps even more important than the prognosis. Here you will find the remedies recommended very numerous, and in many instances directly antagonistic. I remember to have read the report of sixty cases of diphtheria, in which it was stated that all the patients were bled, and all recovered. Such reports show the possibility of making mistakes in diagnosis, and the possibility of finding people who can stand depletion in an extraordinary manner.

We have first to consider the constitutional, and then the local treatment. The constitutional treatment is not less important than the local. Diphtheria is the disease *par excellence* in which stimulants are most important from the beginning. I am an advocate of moderation in the use of stimulants, both in health and disease, but in diphtheria we have an exception. I would advise you to give brandy diluted with water, or port wine and water, from the beginning of the attack. Do not wait for your patients to become exhausted, but stimulate them from the first. When they are beginning to recover, light wines are particularly useful. You must give stimulants not only during the day, but during the night in a large number of cases. I have seen many cases where I believe patients have died because stimulants were not administered during the night. Frequently it is advisable to wake patients to give them stimulants, if they sleep more than four hours. It is important not to let your patient get depressed, and to give stimulants from the first.

I will now pass from the use of stimulants to the use of medicines. Of these the most useful, I believe, is the perchloride of iron. Dr. Jacobi has found this remedy more useful than any other. For general constitutional purposes there is no better remedy. It should be given in full doses. We generally give the tincture or a solution of the perchloride of iron. It is important to give a per-salt. As Dr. Jacobi says, you should give at least a drachm a day; fifteen drops well diluted with water, four times a day. The only times I have not given it is where I have been trying the effects of local remedies, and did not wish to have the results affected by constitutional remedies.

Quinia is of great value in cases having high temperature. These two drugs, perhaps, may be considered the most important constitutional remedies.

All sorts of specifics have been recommended. I have not had any particular success with these remedies. Chlorate of potash is probably the most important. I wish to call particular attention to a remedy introduced by one of your professors, Dr. Beverly Robinson; I refer to cubebs and copabia. These drugs, as many of you may know, have a peculiar influence upon mucous membranes. I have made use of the French pearls coated with sugar, which are readily taken by children, and have had very gratifying success. I have used them principally in the catarrhal form of diphtheria, where the secretion is not very adhesive, and where there is a good deal of catarrh in connection with the false membrane. When there is an epidemic of diphtheria you get a large number of catarrhal cases and in these you will find the pearls to work well.

We pass from the general to the local remedies. Here we have a very wide field. A great many doctors go through life and see very few cases of diphtheria. Some doctors meet with only mild cases, others with severe. Some physicians will tell you they have never lost a case, and will recommend some such simple remedy as chlorate of potash. These statements you should regard with suspicion. Of simple local remedies, lime water and lactic acid are probably the best. One thing in their favor is that they can do no harm. It is a good thing in applying remedies, to have those which can do no harm, even if they do no good. These are much better than strong hydrochloric acid or nitrate of silver, drugs which were formerly used. Strong caustics, we now know, cause an extension of the disease, or an increase in the formation of false membrane, as it is called. Therefore, when we were told by the German physicians that lactic acid and lime water

were efficient remedies in diphtheria, it was very acceptable news. I should state also that solutions of potash have been found very useful. These solutions have a marked effect upon the false membrane. They will gradually dissolve it, as you can demonstrate to yourself by placing some false membrane in a glass of water with the potash. In the living subject, however, where there is a constant reproduction of false membrane, it is a different thing. I have found when I used locally a solution of potash strong enough to dissolve the false membrane, it had an irritating effect. With regard to lactic acid and lime water the result is somewhat different. They do not appear to affect false membrane placed in a tube of water, but in the living subject they certainly do have a dissolving effect upon the false membrane.

It is always difficult to determine the exact effect of any local application upon the false membrane in the throat, on account of the difficulties attending inspection, especially in young subjects, among whom the disease usually occurs. I once had the opportunity, however, of trying those remedies where I could observe their effect. The membrane was situated upon the inside of the lip. I treated one side with lime water, while no applications were made to the other. The side treated got well fastest. I mentioned this detail in passing as opposed to Dr. Jacobi's idea that the influence of these remedies has been over-estimated.

We pass on to another class of remedies, namely, those which have the effect of shutting out the air. These have been used considerably in England but not much, so far as I am aware, in America. I tried some experiments a few years ago of dissolving different gums in ether, chloroform, and alcohol, and I found as a result of a considerable number of trials, that tolu in ether, in the proportion of one part of the former to five parts of the latter, made a good varnish, one that was strong and would not crack, and furthermore, was not irritating when applied to mucous membranes.

Many of these local remedies have been recommended on the ground that they destroy germs. I omitted to mention carbolic acid and salicylic acid as among the most useful of local remedies. Carbolic acid is a very great germ destroyer. All of this class of remedies have been recommended upon the scientific ground that they destroy germs.

Now the principle which I introduced was this: no matter whether it is an animal germ, or vegetable growth, or something else that causes this false membrane to be formed, whatever it may be, it requires the presence of air in order to develop. By excluding the air, we arrest its growth. Hence when I have a patient with diphtheria, I exclude the air from the surface of the affected mucous membrane by the application of tolu varnish. This varnish is in fact a germ destroyer, for germs can not grow without air.

Some of my friends have found difficulty in applying the varnish. The first method of application which I adopted was to wipe the surface dry with a piece of blotting paper, and immediately afterward apply the varnish with a camel's-hair brush. This answers very well when you can do it, but very often the patient retches a little just after you have wiped the surface dry, and again covers it with mucus. To avoid such an accident, I adopted the plan of winding a piece of lint around my finger, wiping the surface dry with this, and then applying the resin. This I have found to answer perfectly well. Even if you do experience some difficulty in the application of the varnish, I advise you to use it.

I have had several patients during the past winter, among the profession, and have had abundant opportunity of testing its value. I shall be exceedingly proud if any of you gentlemen in future times will try the effect of this varnish.

There are only two other points connected with the local treatment of diphtheria that I will call your attention to, namely, the use of steam and ice. Both are very useful, but have to be employed under different circumstances. Ice in the early stages of the disease is often of the greatest comfort to the patient. Small pieces should be frequently taken into the mouth. Its effect is to restrain the inflammation, and if we can do this, we at once diminish the vigor of the attack; so that in the early stages of the disease, you cannot use too much of it.

Now as to the use of the very opposite remedy, namely, steam. I believe it was first recommended by Drs. James, of London, and Oertel, of Munich. Germans always give a philosophic reason for the use of remedies recommended by them. Dr. Oertel says that the effect of steam is to separate the false membrane. True it is that in certain stages of the disease steam is very useful. This is when the false membrane is beginning to separate. I do not believe it is of any use in the early stages; if used then, I think it lowers the powers of the patient. Hence you will have no difficulty in deciding when to use ice and when steam—you are to use ice in the early part of the disease and steam later.

You can make use of some antiseptic, such as carbolic acid or salicylic acid, in conjunction with the steam. It is especially desirable to do this, because at this period of the disease you will find a certain amount of gangrene, and consequently a good deal of fetor. Antiseptics will correct this. These constitute all the points under this head which I will bring to your notice.

I will make a few additional remarks in regard to the performance of tracheotomy in cases of diphtheria. I am very proud to see Dr. Cohen of Philadelphia, present, who has published one of the most complete essays on tracheotomy in the English language. He concludes that the operation should be performed at an early stage. My advice is the same; operate early. When there is considerable false membrane in the larynx, when you see the falling in of the sternum with each inspiration, then is the time for tracheotomy. You should always examine the condition of the thorax, and the posterior part of the chest, to see that the air is going into both lungs. If you find one lung is obstructed I would not operate. But still there are cases where every indication seems to be against operating, and yet the life of the patient is saved by operating. Under such circumstances the question is not whether you or the parents will take the risk, but whether the parents and friends are sufficiently sensible, should the patient die, not to attribute the death to the operation. It is perfectly useless to perform an operation where there is scarcely any chance for recovery, and the probabilities are that it will bring into discredit the whole domain of surgery. You should consider not only the interests of the child but the interests of surgery, for in this way only are we to retain the respect and confidence of the public. If you perform tracheotomy as a rule, perform it early. By so doing many cases that otherwise would result fatally will recover. Of course, if you operate very early a good many cases will recover, for the reason that you will probably operate on cases that do not require it.

By adopting the plan of treatment I have hastily sketched, I feel confident you will meet with your share of success in handling these cases, and will rescue many patients from imminent death.

ORIGINAL ARTICLES.

RUPTURE OF THE SPLEEN.

BY P. J. MURPHY, M.D.,
SURGEON IN CHARGE, COLUMBIA HOSPITAL, WASHINGTON, D. C.

H. K. W., white, æt. 25 years, born in Washington, D. C. Is of nervous temperament, has always enjoyed good health, and led an active life, is of more than ordinary intelligence, having graduated with distinction from Yale in '79, and later from one of our law schools.

He went out to Colorado in the spring of 1882, to visit some friends. He stopped at their ranche, about 600 miles south-west of Kansas City, and 86 miles from a railroad, or physician. While out riding, Friday, March 10, at 3 P.M., was struck in the left side, by a projecting fence rail, and thrown from his horse, remaining senseless for three hours.

Mr. F., his friend, describes the accident in the following manner: "You were riding a horse, and he ran so near the fence, that your left side struck against a fence rail, and you were thrown twenty feet on your back. You did not recover sufficiently to know how you were hurt till the next day. The only thing that you complained of was the pain in your side, and not being able to keep anything on your stomach. You were weak, nervous, and restless, from first to last, but no more nervous and restless than a person of your temperament would be when suffering severe pain. You suffered excruciating pain, part of the time in the bowels, in consequence of cathartics, which it had been thought best to administer; a part of the time in the stomach, apparently from some other cause, to me unknown, and a part of the time also in the injured side. You seemed to suffer almost constantly, sometimes more, sometimes less severe pain, with not infrequent paroxysms of actual suffering. These paroxysms were more severe, and more frequent in the night than in the day. You slept but very little, and that little was at short, infrequent, and irregular intervals, and I think was entirely the result of opiates. You had some fever, and no appetite. You sometimes seemed to relish a glass of milk, or an orange, and on one occasion were pleased with chicken broth. You would sometimes eat a little toast, or taste of meat, but it was without relish, and frequently caused you great distress. You adopted all expedients to find a comfortable position, both by day and by night. You tried the easy chair, the lounge, and the bed, both the sitting and reclining postures, but no position was easy. Throughout the whole, your mind was perfectly clear and active. You comprehended the entire situation, were quick to devise expedients, and ever thoughtful of your friends, and in the intervals of comparative freedom from pain were lively and agreeable in conversation."

The following is the letter of Dr. Sloan, of Kansas City, who was called to take charge of his case, four days after the accident.

"In reply to yours of the 31st ult., I can only state from memory, as I took no notes of your case, I found you, besides some external bruises and abrasions, suffering pain in the left side of chest, increased on full inspiration, with slight friction sounds on auscultation. Tenderness over the spleen with some enlargement. Pulse about 80, temperature 100°. The action of a cathartic provoked so much tormina, as to require an opiate. Discovered no fracture, aneurism, or other internal injury. This is my recollection of your case four days after your injury. Am sorry that I did not take full notes of your case."

. . . . . .

I was called to see Mr. W. on Sunday, March 19th, at 10.30 P.M., and found him much exhausted from the long journey he had taken, having travelled from Kansas City to Washington without intermission. His skin was cold and clammy, pulse 96, eyes sunken, face haggard, and all the symptoms of intense exhaustion. He complained of great pain in his left side. A cursory examination was made, in order to determine the nature and extent of his injury. A critical examination was deemed unadvisable for the present. No fracture of rib was discoverable, there was resonance on percussion over the left chest, expiration slightly exaggerated. There was circumscribed flatness over the region of the spleen, with tenderness on percussion. Hot applications were placed over the left side, covered by an oil-silk jacket, and Pulv. ipecac. comp., gr. v, in capsule, was directed to be given every four hours, till sleep was induced. A small quantity of beef broth, with a wineglassful of sherry wine, was administered, and the patient left to the care of friends for the night.

20th, 10 A.M.—Slept pretty well through the night, except when awakened by the pain in left side. Patient states that he can breathe better, and that the pain is bearable. Bowels not having opened for several days, an enema of soap-suds was directed, which had the effect of bringing away a large mass of feces, cylinder-shaped, and very thick. Directed the following recipe to be taken every four hours:

R.—Hydrarg. chloridi mit.,	.	gr. j.
Bismuthi subnit.,	.	3j.
Sodii bicarb.,	.	3ss.
Pulv. carbo. lig.,	.	gr. xxiv.

M. et div. in chart. No. xii.

Temperature in axilla 99.4°, pulse 98, small and thready.

6 P.M.—Continues about the same; mouth feels dry and clammy. Has a great craving for food and drink. Diet restricted to beef tea (a teacupful) every four hours.

21st, 10 A.M.—Passed a restless night. Complains of great sinking in pit of stomach, and wishes a good drink or a "square meal."

22d, 10 A.M.—A careful examination was instituted. The margin of dulness had extended further down below the false ribs, and fluctuation was discovered. The condition of the patient not improving, and he apparently getting weaker from day to day, a consultation was decided upon by the family, and Dr. Robert Reyburn selected as the medical adviser.

April 6.—Dr. Reyburn agreed as to the presence of a circumscribed swelling, and the presence of fluid, also the advisability of introducing an exploring needle to determine its character. This was communicated to the family, but the operation was deferred till the following day.

7th.—The tumor or swelling was not so prominent, but the area of dulness had increased. This led to the further postponement of operative interference. The pain in the side had now subsided, but constant suffering was complained of in umbilical region. Had hot water-bags applied over abdomen constantly, to relieve this pain. The increased desire for food persisted through all this time, and the stools were unusually hard and copious. The same sense of sinking at the pit of stomach was complained of, and especially on assuming the sitting posture. The patient was evidently losing flesh, very nervous and excitable, and was frequently aroused through the night by the pain around the navel, and would at intervals belch and be somewhat nauseated. Was very petulant, fretful, and complained because he did not get well more rapidly. Four days after the first consultation, a diarrhœa set in, the stools being slightly bloody, and, on account of the sudden and marked flatness of the swelling, it was thought that the circumscribed swelling had communicated with, and was evacuating its contents into the large intestine. There was during this time no marked febrile condition. Accurate thermometric observations were taken twice daily, and the readings at no time exceeded 100.2°, but on one occasion was .3° below normal.

Sunday, May 14.—Patient has been sitting up in a reclining chair for a few days, and thinks he notices the lump in his side to be larger. Upon examination, such is found to be the case. A small needle of the aspirator was introduced, and three pints and four ounces of fluid withdrawn. It was deemed unadvisable to remove the entire contents of the swelling, as the patient seemed to weaken, and presented symptoms of impending shock, and I feared that I might be dealing with a traumatic aneurism (of some of the branches of the splenic to the spleen, or the vasa brevia), rather than a laceration of the spleen. I administered a wineglassful of whiskey, and had the patient put to bed. The fluid was examined by my assistant, Dr. Johnson, who gave the following report:

Amount three pints, and four ounces.

General appearance: when viewed all together, the color was dark cherry-red, but when examined in less amount, was considerably paler. It was slightly viscid. Reaction alkaline, specific gravity 1035. Upon the application of heat it became more viscid, and would fly out of the test-tube if it was held in the flame any length of time. HNO_3 would make it less viscid, and throw down a granular deposit similar to that in beef-tea.

Microscopical appearance: blood corpuscles (red) in great numbers, some normal, others crenated, leucocytes, or white blood corpuscles, three or four times the normal amount, and in some budding was in progress; some oval, with from one to two, or more processes, others dumb-bell shaped, plates of cholesterine, mucus.

May 15, 10 A.M.—The removal of the fluid seemed to relieve the sinking sensation at the pit of the stomach, and he is apparently in better spirits, and is delighted that the swelling has disappeared, as its presence caused him a great deal of anxiety. From this date the patient began steadily to improve, and on June 7, left for Nantucket.

He retured to the city August 28, and on September 23, I made a careful examination of my patient in company with Dr. Johnson, and the following facts were noted. The general appearance of the abdomen is symmetrical on the two sides. There was slight dulness on percussion below the normal margin of the spleen. Taking the point of puncture made by the needle of the aspirator, which was at the centre of the circumscribed swelling, that point is 5½ inches from ensiform cartilage, 2⅜ inches from linea alba, and 7¾ inches from the nipple, on a line passing through it drawn parallel with the body.

In considering injuries of the spleen, its location and relation to the other organs are of primary importance. It is of an oblong flattened form, very friable, and highly vascular, situated in the left hypochondriac region embracing the cardiac end of the stomach.

It is covered by peritoneum, but like all the other abdominal viscera not entirely so. The external surface smooth and convex, is in relation with the under surface of the diaphragm, which separates it from the ninth, tenth, and eleventh ribs of the left side. The internal surface is divided by a vertical fissure, the hilum, into an anterior larger, and a posterior smaller portion. The hilum is pierced by several irregular apertures for the transmission of vessels and nerves and from its margins are reflected the two layers of peritoneum, which invest the organ, on to the cardiac end of the stomach, forming the gastro-splenic omentum, which contains between its layers the splenic vessels, and nerves, also the vasa brevia. The upper end is thick, and rounded, and in relation with the diaphragm, to which it is connected by a fold of peritoneum—the suspensory ligament. The lower end is pointed and in relation with the left extremity of the transverse colon, etc., and is on a line with the lower edge of the ribs. The external, or serous coat is derived from the peritoneum, and is intimately adherent to the fibrous elastic coat. It invests almost the entire organ, being reflected from it at the hilum on to the cardiac end of the stomach, and at the upper end of the organ on to the diaphragm. Now it is easy to see how, from an injury to the organ at this point, or of the vessels, hemorrhage or effusion taking place, that it would be confined between the layers of peritoneum, hilum of spleen, and cardiac end of stomach, and thus prevented till a rupture of one of the walls of this space, from over-distention or otherwise, from gravitating to the more dependent portions of the abdominal cavity, and we would naturally get the following physical signs: slight distention of the abdomen at this point, fluctuation, and circumscribed dulness on percussion.

There are several facts in connection with this case which are worthy of mention.

1st. The rarity of the disease, and still more rare is recovery.

2d. That no ribs were fractured, which is unusual, in so far as I have been able to determine.

3d. The location and character of the swelling were, unmistakably, traumatism to the vessels of the spleen pulp. There was no bruit or thrill peculiar to aneurismal tumors, and the condition of the fluid evacuated showed that it was separated or shut off from the general circulation.

4th. The inordinate desire for food, the modification of appetite and disposition, were well marked, and apparently bear no slight significance to the results obtained in physiological experiments on this organ.

5th. The remarkable change for the better which took place after the removal of the fluid, and the patient's restoration to health after so grave an injury, as the external violence sufficient to produce such an injury is in itself almost always fatal.

THE TREATMENT OF FRACTURE OF THE CLAVICLE.

BY HARVEY L. BYRD, M.D.,

PRESIDENT AND PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN, IN BALTIMORE MEDICAL COLLEGE, ETC., BALTIMORE, MD.

EVERY surgeon of much experience in treating fracture of the clavicle, must have been struck with the inadequacy and want of adaptability of several forms of apparatus in general use, or employed in the management of that accident at the present time; and has had occasion for annoyance and disappointment at the result of its treatment, in some cases at least, even after the most careful attention, and when circumstances seemed to encourage the hope of a better result.

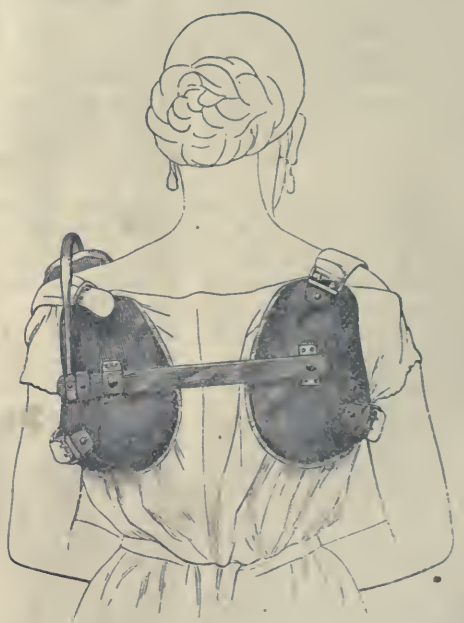
A description of fracture of the clavicle is unnecessary, of course, in an article intended for the perusal of medical practitioners, and a presentation of the anatomical structures, and the relations of the parts involved in the accident would be as superrogatory as an account of the lesion itself, at the present day. Nor is it deemed either requisite, or necessary, in a brief journal article, to comment upon and criticise the various appliances which have been, or are now, in use, in the treatment of this particular trouble.

I will, therefore, only remark, that after more than the third of a century of active professional work, four years of which were passed as an army surgeon in the field, and as chief of two large military hospitals; that my opportunities have been ample for contrasting the merits of the more popular appliances used in the treatment of such cases.

During this long period of time, I have found that though success was often attained, and satisfaction with the result of the treatment secured to the patient, that these important ends were reached without special regard to the particular apparatus employed, *i. e.*, the surroundings, and conformity of the patient to the instructions given him, were factors of equal, if not superior, value to the mechanical appliance that was used for his relief.

Practitioners are aware of how difficult a matter it is, sometimes, to keep patients quiet sufficiently long to secure proper union of the fractured ends of the bone, arising mainly from the apparently trifling character of the injury; and hence, the necessity for the use of an apparatus which *will* keep the broken ends in apposition, in every case, and allow at the same time of exercise in the open air, if the patient chooses to take it.

Experience will show that this important desideratum has been fully met in the apparatus represented in the accompanying cut; and it will be seen that there are improvements which meet all the other requirements involved in fracture of the collar bone, viz: extension and counter-extension; freedom in the movements of the ribs and muscles concerned in respiration, etc. etc. Thus, it would seem, there is absolutely nothing more needed as a mechanical appliance for the scientific and successful treatment of such fractures, when this instrument is properly adjusted. The use of an ordinary sling or handkerchief will give all the comfort and support that is required for the elbow and forearm, when the patient desires to be up.



The apparatus has been submitted to several of my *confrères* and professional friends, and their verdict, after careful examination, has been a hearty approval of its merits. It will be readily perceived, upon an inspection of the cut, that all the necessary leverage for reducing the fracture, and keeping the broken ends of the bone in apposition, is obtained by means of the two plates in their action upon the inferior angles and dorsi of the scapulæ, which serve as fulcrums for drawing and keeping the shoulders backwards, and for the attachment of a special lever for action, as necessary, upon the shoulder of the fractured side. Thus the shoulder-straps, attached

by buckles to the superior and inferior lateral margins of the plates, may be so adjusted as to meet all the requirements of a majority of cases, without bringing the special lever for the shoulder into requisition at all; and when the ordinary sling is added for the comfortable support of the elbow and forearm, the usual bandage, axillary pad, etc., become entirely superfluous and unnecessary. Any amount of leverage that might be desired, however, can be readily added to the apparatus by attaching buckles to the inferior lateral margins of the plates, for securing and properly adjusting a piece of webbing around the front and sides of the chest. (These buckles do not appear in the cut.) From what has been said above, it will be readily perceived that the apparatus is well adapted to a larger field of usefulness than that of fracture of the clavicle, valuable as it is in that trouble. Such cases, for example, as stooping of the shoulders, as is often found in schoolgirls and boys, in hump or round-shoulder in the adult, etc.

Description of the Apparatus.—Reference to the cut will show it to be composed of two metallic plates, of sufficient size to cover the scapulæ of an adult person. These are connected together by means of a flat steel bar, to which is attached a lever, extending over and fronting the anterior apex of the shoulder, through the distal extremity of which passes a thumbscrew from before backwards, and to the end of which a concave metal plate is attached, with its concavity looking to the anterior apex of the shoulder. This lever is adapted for transference to either shoulder. Screws are used for keeping the several parts in their proper places, and to allow of the adjustment of the apparatus to persons of different sizes. All parts of the instrument that come in contact with the surface of the body of the patient are nicely padded.

I am indebted to the skilful workmanship of the Messrs. F. Arnold & Son, instrument makers, of this city, for the accuracy and faithfulness with which they executed my design, and from which the accompanying cut was taken.

127 Arlington Avenue.

MEDICAL PROGRESS.

Hyoscine.—This alkaloid is as yet not much known. Mr. Snell's experience with it up to the present is not extensive, but he believes that it possesses qualities which will probaby bring it into vogue. Two salts of hyoscine have been supplied to him—a bromide and an iodide. At first he used a solution of the strength of the ordinary atropia one (2 gr. to 1 oz.), but after reading the abstract of a paper by Emmert (abstracted from the *Archiv für Augenheilkunde*, in the *Ann. d'Oculist.*, vol. ii., 1882, p. 51, and *Practitioner*), of Berne, on this alkaloid, it appeared to be unnecessary to do so. He states that a drop of one-tenth per cent. hyoscine solution is more rapid and more manifest on the pupillary sphincter and the accommodation than a drop of atropia solution of one-half per cent. He can bear out this statement as to the rapidity of action on the pupil, as dilatation certainly takes place quicker than with atropia. He does not know, however, that its effect passes off in a much shorter time than atropia; nor does his experience allow him to say anything as to its efficacy as an accommodation paralyzer. Undoubtedly it is a powerful pupil dilator, and it is asserted to be more serviceable for breaking down iritic adhesions than the other mydriatics. In one case in particular, with numerous adhesions, which yielded little to atropia (2 gr. and, he thinks, 4 gr. solution), and with no appreciable change in the vascularity of the ocular surfaces, and this notwithstanding the internal administration of hydrarg. perchlor.; here the substitution of (1 in 1,000) hyoscine solution produced a somewhat wider dilatation of pupil, and the rapid disappearance of the surface vascularity.

The present price of the drug is high, but independently of the necessary reduction with increased demand, the weakness of the solution used materially reduces the cost. It should be added that Emmert, in his paper, refers to the hydriodate of hyoscine.—*Ophthalmic Review*, October, 1882.

Bacteria of Venereal Diseases.—Dr. Leistikow (*Deutsche Med. Zeit.*, No. 36) was unable to find any specific bacteria in the hard or soft sores, but was successful in the case of gonorrhœa. It is affirmed that a specific can be distinguished from a simple urethral discharge by the aid of the microscope. The microbes are only sparingly present in the stage of acute inflammation with profuse thick pus; their numbers are greater in the thin milky discharge of chronic gonorrhœa. They were discovered also in a case more than a year old; this is held to demonstrate the danger of infection at that date. Birch-Hirschfeld, like Klebs and Aufrecht, was able to find bacteria in syphilitic new formations in the brain, lungs, liver, stomach, and bowels; they were most abundant at the limit of the granulation tissue. Fuchsin was the dye used. Condylomata, hard chancres, and a papilla from a papular syphilide were taken fresh and examined for the sake of comparison. Microzymes were richly present in the cells of the rete Malpighii and in the connective tissue of the papilloma. Nothing was made out of the blood. The individual bacterium is a very short (μ, one micromillimetre) and relatively thick rod, with the ends rounded off; in some preparations a spindle-shaped group was formed of rods three to five times longer, lying parallel to one another. Besides these existing free in the tissues, others (of the smaller sort) were seen *in* the cells of the granulation tissue.—*Med. Times and Gazette*, Sept. 30, 1882.

The Incubation Period of Scarlet Fever.—In his last annual report on the health of the Newmarket Rural District, Mr. Armistead refers specially to an outbreak of scarlet fever as one of peculiar interest, as serving to throw considerable light upon the still doubtful points of the duration of the infection in scarlet fever, and also upon the period of its incubation. An outbreak occurred in a village early in the year, and the disease was carried by one of the cases to another village (Westley), where every precaution was taken. But when the outbreak was nearly ended, a man from a different part of the district (Bottisham Fen) took his wife and three children in a cart to Westley on August 12th or 13th, and stayed next door to a child who had been ill with scarlet fever for six weeks, but had finished desquamating, and was so far recovered that she and the children from Bottisham Fen were allowed to play together. They went back to Bottisham Fen on the following day, and on August 19th the scarlet fever rash was distinctly seen on all three children simultaneously. The disease spread to six other children in the Fen, and to two others in another village. With regard to the duration of the fever, Mr. Armistead states that the child at Westley sickened on July 2d, the children from Bottisham Fen came in contact with

the child at Westley on the evening of August 13th, and on the following morning—the whole of the period of exposure to infection being only about twenty-four hours—and then they returned home. To Mr. Armistead's mind these facts show that the infection of scarlet fever will last six weeks at least, and be apparently as strong at the end of that time as ever it was. As to the period of incubation on August 14th: the children were removed quite away from any source of infection; on the 19th, the rash was out; and the disease actually began on the 18th, after a period of incubation of four days, or about ninety-six hours, which is the same as Mr. Armistead has found in two former cases which he investigated.—*British Medical Journal*, Sept. 30, 1882.

The Transmission of Syphilis.—From observations made on one hundred and nineteen syphilitic families, Kassowitz comes to the following conclusions:

1. A healthy woman can, without herself being infected, bear a child who inherits syphilis from its father.

2. A child may be born untainted if its parents, at the time of conception, are healthy, even if the mother should acquire syphilis during her pregnancy.

Caspany is strongly opposed to this view. Even if one holds that the syphilitic poison is located in the cellular elements, the impossibility of their diapedesis into the fœtal blood has never been proved. Caspany has, moreover, succeeded in finding granules of cinnabar in great number in the blood of the fœtus in pregnant rabbits in whose jugular vein he injected an emulsion of cinnabar. He does not state as to whether this transfer occurred through the white corpuscles or not, but this mode is rendered probable from the experiments of Max Schultze.

Generally, the conditions demanded by Fournier as to the advisability of marriage of syphilitics are accepted.

1. At least three to five years must have passed from the date of infection.

2. Thorough mercurial treatment must have been employed.

3. If either or both parents are syphilitic before conception, the child may become syphilitic.

4. If both parents are sound at the time of conception, and the mother subsequently becomes syphilitic, the disease may be transferred through the placental circulation, and the child be born with congenital syphilis.

5. If the father is syphilitic before the conception, and the mother sound and not infected by the father, the syphilitic poison may reach the mother through the placental circulation from the child, and the mother either rendered syphilitic or her constitution so changed that she obtains an immunity to the disease.

The last opinion is only advanced with considerable reserve.—*Deutsche med. Woch.*, July 29, 1882.

The Contagion of Phthisis.—Dr. C. T. Williams read a paper with this title before the Section of Medicine at the recent meeting of the British Medical Association. His conclusions are as follows:

1. The evidence of large institutions for the treatment of consumption, such as the Brompton Hospital, directly negatives any idea of consumption being a distinctly infective disease, like a zymotic fever.

2. Phthisis is not, in the ordinary sense of the word, an infectious disease; the opportunities for contagion being most numerous, while the examples of its action are exceedingly rare.

3. In the rare instances of contagion through inhalation, the conditions appear to have been—(1) close intimacy with the patient, such as sleeping in the same bed or room; (2) activity of the tubercular process, either in the way of tuberculosis or of excavation; (3) neglect of proper ventilation of the room.

4. In addition to the above, a husband may, though he rarely does so, infect his wife by coition: and this risk is considerably increased in the event of pregnancy.

5. By the adoption of proper hygienic measures, such as good ventilation, and separation of consumptive from healthy people at night, all danger of infection can easily be obviated.

Mr. Robert Robertson also read a paper with a similar title at the same meeting. He expresses his conclusions as follows:

1. Among one hundred individuals affected, about one-third have recognizably been exposed to the disease within a period having an appreciable connection with the onset of their own illness.

2. Among married couples, of which one person has been affected, there has been immunity from disease in the other person in, at least, 80 per cent. of those inquired into; and that, among the children in the families represented by patients under observation, immunity from disease occurred in nearly 69 per cent.

3. The existence of phthisis in members of the preceding generation was attended with an increased frequency of its occurrence in the succeeding one, amounting to nearly 13 per cent. Hence it may be concluded that:

1. Probably, in every case of phthisis, the inception and presence of a specific bacterium is essential to the destructive process.

2. Probably there is a certain risk of communication of the disease to unaffected persons, and, *cæteris paribus*, the greater, the more intimate the association.

3. Continued association with a consumptive person is probably not in itself sufficient to originate the disease in any instance.

4. The preparation of the lung-tissue by a chill, debility, etc., is probably as essential to the destructive process as the presence of the specific bacterium itself.—*British Medical Journal*, September 30, 1882.

Operative Treatment of Strangulated Hernia.—Dr. Rochelt reports a case of a man, aged 54 years, in whom a right-sided inguinal hernia had existed for many years without giving any trouble, but which finally became irreducible and caused symptoms of strangulation. The operation showed that the intestine was ruptured in three places, and that a large portion of the gut, about 12 cm. long, was gangrenous. This portion was resected, and the two ends of the divided intestine united by means of Lembert and Czerny's sutures; a drainage-tube was inserted in the canal, and the external wound dressed after Lister's method. The patient died of collapse eight hours after the operation.

Dr. Rochelt also reports three cases of herniotomy for strangulated femoral hernia, in all of which the operation resulted favorably.—*Wiener med. Presse*, September 17, 1882.

Boric Acid in the Treatment of Boils.—Dr. Garrigues states that recently he has employed a paste of boric acid in a number of cases of boils on the face and neck, invariably with the most satisfactory results. The combination he uses is the following:

Powdered boric acid,	4 grammes.
Vaseline,	20 grammes.
Benzoin powder,	0.50 centigrammes.

This ointment is perfectly non-irritating, and can be preserved indefinitely. The boric acid should be incorporated directly with the vaseline, and not first dissolved in glycerine or alcohol, or it will cause irritation.—*Journ. de Médecine de Paris*, Sept. 23, 1882.

Fatty Degeneration of the Liver.—The diagnosis of fatty degeneration of the liver is often extremely difficult—impossible unless the organ is enlarged, and when it is increased in size often doubtful, since the characters of this enlargement are common also to others. MM. Lépine and Eymonnet have drawn attention to a new symptom of the condition, which they believe to be of considerable practical importance. The former, two years ago, called attention to the value of an estimation of the biliary sulphur of the urine as an evidence of the degree of activity of the liver. The indication now pointed out is drawn from the same source. The phosphoric acid of urine, which is in the form of phosphate, is completely removed by treating it with the magnesian solution and baryta water, so that the filtrate contains no trace of phosphoric acid. The liquid is then evaporated, the residue calcined with nitrate of potash, redissolved in water acidulated with nitric acid, and treated with the magnesian solution; a little phosphoric acid will be found, which has evidently been newly formed. This is produced by the destruction, at the moment of calcination, of the phospho-glyceric acid normally contained in the urine, and which forms an integral part of lethicine. In the normal condition the quantity of phosphoric acid thus produced in normal urine is extremely small, and does not exceed a centigramme—*i. e.*, not more than the two-hundredth part of the amount of urea contained in the same volume of urine. In several cases of fatty liver the observers have found that the amount, in proportion to the urea, was increased five-fold, or even ten-fold. At present, in no other condition, physiological or pathological, have they met with a similar increase. To what is this fact to be ascribed? Some years ago Dastre and Morat pointed out that the fat of the liver, like many other forms of fat found in the economy, contains lethicine. Lépine and Eymonnet have verified this statement by the direct analysis of livers which were in a state of fatty degeneration, and they have found, moreover, that the amount of lethicine under these circumstances is very large, amounting to no less than 3 per cent. of the fresh organ, and 15 per cent. of the dried tissue.—*Lancet*, September 23, 1882.

The Estimation of Peptone.—Schmidt-Mülheim uses the red color which a solution of peptone assumes on the addition of sodium hydrate and cupric sulphate. To make a standard solution a convenient known quantity of peptone is taken and dissolved in water. To this solution sodic hydrate is added, and then a weak solution of $CuSO_4$ until the wine-red color begins to change into blue, whereupon the entire mixture is diluted with water so that three thousand cubic centimetres contain exactly one gramme of peptone. To determine the amount of peptone in a given liquid (from which other proteids have been removed) a small amount of sodic hydrate is added, and then just enough $CuSO_4$ to bring about the change from wine-red into blue, as in preparing the standard solution. This being done measured quantities of each are brought into little glass boxes with perfectly parallel sides, standing in a good light and against a white background. Over these boxes are burettes from which water is allowed to drop until the colors of the solutions to be compared are identical, after which a simple calculation gives the amount of peptone present. This method has, of course, all the objections of colorimetric methods in general. Schmidt-Mülheim found its extreme error to be + six per cent.—*Boston Med. and Surg. Journ.*, September 28, 1882.

Hydatid Cyst of the Heart.—M. Arnold (*Gaz. des Hôp.*) reports the case of a young man, 21 years of age, who had been subject to fainting spells—heart's action energetic but the pulsations regular and normal—cyanotic condition of skin, without true respiratory embarrassment, general and confluent urticaria, manifest tendency to algidity. The autopsy discovered three hydatid cysts at the apex of the left lung; in the pulmonary artery numerous free hydatids of all sizes, still more hydatids in the right ventricle. In the right auricle a cystic tumor semi-collapsed with an enlarged slit-like opening towards the tricuspid orifice and filled with hydatids; the liver and spleen contained no cysts. —*Canadian Journ. of Med. Science*, Oct. 1882.

Detachment of the Retina. — Denissenko (*Aerztl. Zeit.*, 1882, Nos. 1, 2, 3, 4, 6) rejects the theories of Iwanoff, Klein, Jäger, Coccius, Adamük, and Rählmann in regard to detachment of the retina, especially that of traumatic origin; he and Schneller point out that these theories do not explain why and under what conditions traumatic detachment is easily cured in one case but remains incurable in the other; he discards entirely Schneller's conception of the lymph-currents in the retina. He admits that affections of the choroid may influence (though not primarily) the detachment of the retina, but maintains that in the retina itself all the conditions for the development and continuation of this pathological process are given.

Based upon his own histological investigations, Denissenko thus explains detachment of the retina. In chorio-retinitis (sometimes independently), atrophy of the rods and cones gradually sets in, extending from the outer to the inner parts and nuclei. Thus cavities are formed in the outer granular layer, which easily unite to form larger ones, and are only bounded by the limitans externa. An injury easily produces a rent in the latter; the lymph escapes from the cavities and penetrates between the retina and choroid, detaching the former. The hyperæmia increases the secretion of the lymph from the retina considerably and thus sustains the detachment.

The detachment is cured when the lymph is prevented from penetrating beneath the retina, either by adhesion of the rods and cones over the rent in the limitans externa, forming an isolated cavity, or by union between the retina and choroid around the rent, with formation of a cavity. The former event is so frequent in owls and horses that the author was at first inclined to consider it a normal condition.

The lymph causing the detachment generally comes from the retina, but sometimes from the choroid; in the latter case, however, detachment can only take place when the tension in the eye is negative.

The changes in the vitreous are only secondary results of the detachment of the retina.—*Archives of Ophthalmology*, September, 1882.

Venereal and Common Warts.—Unna (*Monatshefte für prakt. Derm.*, 1882, Band 1, No. 3, p. 96) recommends for the treatment of condylomata acuminata and ordinary warts the continuous application of unguent. hydrarg. containing five per cent. of arsenic. In the case of a young girl upon whose hands were a hundred or more warts, the unbroken application for three weeks of a plaster containing in each 0.2 square metre 10 grammes of arsenic and 5 grammes of mercury, caused entire disappearance of the disease without any irritation of the normal skin. Cure was effected not by reason of necrosis and destruction of the warts, as after the use of caustics, but by resorption, as in cases of spontaneous cure.—*Boston Medical and Surgical Journal*, Oct. 5, 1882.

Blennorrhœa Neonatorum.—According to Haussmann, in a recent monograph on this subject, most cases

of blennorrhœa neonatorum are due to infection with the vaginal secretion of the mother, though the lochia or the sero-purulent secretion of a sore nipple or inflamed breast may also be the cause. It may also be produced by pus from a sore upon the child, or by foreign animal tissue, especially pieces of the placenta placed upon the eyes. One eye may also infect the other, or it may be conveyed upon the eye by the substances used in oiling the finger or for local application. In order to prevent the infection every woman should be cautioned to check while yet pregnant any discharge of the genital organs. If an increased secretion is not noticed until the beginning or during the course of the birth, a moderate mucous secretion may be stopped so completely by prophylactic irrigation and careful disinfection of the vulva in case of a moderately long birth-act of a multipara, that it is sufficient to disinfect the eyelids after the head is born in order to prevent infection. If there is a profuse purulent, or thin serous discharge, however, the genital organs must be frequently cleansed. The lids and their surroundings should be carefully disinfected after the birth of the head, and before they are first opened, in order to prevent any infectious substances from reaching the conjunctiva. If it is impossible to amplify these prophylactic measures before the eyes are opened, a two per cent. solution of nitrate of silver should be dropped into the conjunctival sac. After the birth of the child great care should be exercised that the lochia or the secretion of a sore nipple does not come in contact with the eye. In lying-in hospitals and foundling asylums the strictest disinfection should be practised, and the children with healthy eyes should be kept apart from those with sore eyes.—*Archives of Ophthalmology*, September, 1882.

PATHOLOGY AND TREATMENT OF RHINOPHYMA.—According to DR. HANS VON HEBRA (*Vierteljahresschrift für Derm. und Syph.*, viii. Jahrgang, Heft 4, p. 603), histological examination shows the normal elements of the skin in a condition of distorted, irregular hypertrophy. The structures in which this hypertrophy is most manifest are the bloodvessels, connective tissue, and the sebaceous glands, notably the latter, which attain gigantic size, and become transformed into cyst-like bodies. The epithelial layers covering the papillæ are the only tissues not participating in the pathological process. Contrary to Wilson's opinion, the affection has nothing in common with elephantiasis Arabum. Rhinophyma never originates with, nor is accompanied by, inflammatory processes, while the true elephantiasis Arabum consists essentially in hypertrophy of connective tissue, due to repeated attacks of erysipelatous inflammation, and in the resulting chronic œdema of the parts. In elephantiasis the œdema, especially in the more recent cases, is so great that upon incision into the diseased tissues, large quantities of albuminous fluid escapes, which is never the case in rhinophyma. In the latter disease the tissues are not soaked with fluid like a sponge, but show infiltration merely of embryonic cells. In elephantiasis the corium and papillary layers of the skin take but little share in the pathological process, which is confined to the subcutaneous tissues, directly the opposite being true of rhinophyma, so that periostitis and consequent new formation of bone, so common in elephantiasis, does not occur in rhinophyma.

The treatment followed by the author, with encouraging results, consisted in paring down the excrescences upon the nose, and carving as good a looking feature as possible out of the shapeless mass. By reason of the existing dilatation of the bloodvessels, the bleeding is often excessive, but may always be controlled by compression. Subsequent treatment is symptomatic and antiseptic, the raw surfaces eventually becoming covered with a layer of sound epidermis, showing here and there only traces of cicatricial tissue.—*Boston Medical and Surgical Journal*, Oct. 5, 1882.

THE INFLUENCE OF TEMPERATURE ON THE DEVELOPMENT OF CHARBON.—M. PASTEUR demonstrated, two years since, that fowls contracted charbon only when their temperature was lowered, their normal temperature being 111° Fahr. M. Paul Gibier has recently determined that frogs contract charbon when under the influence of relatively high temperature. He placed twenty frogs in tepid water, and inoculated them with charbon virus; five of them contracted the malady. Their blood indicated the presence of bacteria. These elements were larger than those observed in the bovine and ovine species. Guinea-pigs and rabbits were inoculated with the blood of the frogs, and contracted charbon.—*Brit. Med. Journ.*, Sept. 30, 1882.

HEMORRHAGIC PACHYMENINGITIS AND THE FORMATION OF NEW MEMBRANES IN THE DRUM-CAVITY.—MOOS and STEINBRUGGE (*Zeits. f. Ohrenheil.*, xi. 2) illustrate the connection between hemorrhagic pachymeningitis and the formation of new membranes in the drum-cavity, by the following case: The patient did not exhibit any loss of hearing, but complained of noises in the ears and similar sensations in his head. He had had an extensive hemorrhage into the optic nerve sheaths, the incarceration of the optic nerves producing choked disks. At the autopsy, in both temporal bones the adventitia of the branches of the internal auditory artery had a glassy appearance, and showed ring-like swellings. There was fresh extravasated blood between the nerves at the base of the left modiolus. The structure of the newly formed membranes in the tympanic cavity was made up of light, finely fibrous, wavy connective tissue, with a few oval or spindle-shaped nuclei. This tissue surrounded large and small meshes of bloodvessels. The vessels were generally small, of uniform size, and had the anatomical structure of capillaries. There were no traces of arterioles. Along the course of the vessels, and in the interspaces between them, were numerous small extravasations of blood. In hemorrhagic pachymeningitis the morbid process follows the course of the meningeal artery; and since the tympanic cavity derives at least a part of its nourishment from this artery, we may consider the membranes as a result of the disease, which passes by preference along certain blood-channels. The diagnosis in the case of the process in the brain was uncertain in the beginning, lying between pachymeningitis hemorrhagica and intracranial tumor. As the diagnosis of the tympanic disease just described can be made with the otoscope on account of the peculiar mixed color of the drum-head, it may be of great service in settling the diagnosis of pachymeningitis.—*New York Medical Journal*, October, 1882.

LUPUS.—The following conclusions are given by DR. RAUDNIZ (*Vierteljahresschrift für Derm. und Syph.*, ix. Jahrgang, Heft 1, p. 81), as the result of the statistical examination of two hundred and nine cases of lupus. Neither anatomically nor clinically can a difference between scrofulous and idiopathic lupus be made out, the disease appearing in the same form in already scrofulous and in entirely healthy individuals. A combination with inherited tuberculosis is only discernible in from ten to fifteen per cent. of all cases. The abscesses of the lymphatic glands, so frequently met with in scrofula, are almost never found in lupus. A contemporaneous manifestation of lupus in blood relations is seen only in the rarest instances, and hereditary transmission of lupus from parents to children

perhaps never takes place. The infrequency of association between lupus and pulmonary tuberculosis decidedly speaks against the identity of these affections. On the other hand, the facts that in at least thirty per cent. of the cases observed, lupus was developed upon or only in the neighborhood of cicatrices due to scrofulous disease, or upon mucous membranes already changed by catarrhal processes; that in twelve cases injury, and in eight cases local attacks of erysipelas were given as exciting causes of the disease, would indicate that lupus is often due to a localized, specific predisposition, the nature of which is entirely hypothetical. The small proportion of cases, seventeen in number, in which lupus was found in combination with often trivial affections of the skin, contradicts the assumption that in lupus we have to do with a generalized predisposition of the skin to pathological changes.—*Boston Medical and Surgical Journal*, Oct. 5, 1882.

The Temperature of the Human Stomach.—Dr. Rodsajewsky (*Deutsche Med. Zeit.*), of Kiew, has been making observations on the temperature of the stomach in a patient with gastro-fistula; the opening had been made for stricture of the œsophagus due to swallowing sulphuric acid. Synchronous investigations were made in the stomach, rectum, and axilla. He finds that the gastric temperature is dependent on two factors—(1) the general diurnal variation of the body-heat; (2) the temperature of the food given. The temperature of the latter diminishes during digestion. The gastric heat is lower than that of the rectum during digestion, but higher than the axillary. The introduction of hot nourishment affects the whole body as well as the stomach.—*Medical Times and Gazette*, Sept. 30, 1882.

Antiseptic Solutions of Atropia.—Mr. Simeon Snell states that for some time he has been under the impression that the irritation caused frequently after the prolonged use of atropia, partaking frequently of a species of granular ophthalmia, was owing to the fungus which so readily forms in solutions of this alkaloid. With a view to counteracting this, he had already used solutions to which an antiseptic (salicylic acid) had been added, when the notice appeared in the Ophthalmic Review (p. 58) on the observations of Kroemer on this subject. He fancies, certainly, that solutions made with salicylic or carbolic acid are better borne than the ordinary aqueous solutions. He has noticed also, though not invariably, that in a case where the watery solution had occasioned irritation, it has become lessened or subsided on the substitution of the antiseptic solution. It seems that those cases in which, perhaps, one application is followed by œdema and swelling of the lids—a genuine atropia erysipelas—belong to a different category than do those resulting merely from the prolonged use of atropia for sometimes weeks or months. The former is more of the character of an idiosyncrasy.

A good plan to prescribe atropia, he believes, is with vaseline. In some cases it is certainly better tolerated in this way, and the vaseline is aseptic.—*Ophthalmic Review*, October, 1882.

An Operating Couch for Venereal Wards.—Dr. O. Peterson writes, in the *St. Petersburger Medicinische Wochenschrift*, a short account of a new kind of couch now employed in the syphilitic wards of the Alexander Hospital, St. Petersburg. In minor operations about the groin and the genitals, the loins and nates of the patient are apt to become soaked in blood, morbid secretions, or lotions used for washing the wound or seat of disease. To avoid this inconvenience, Dr. Peterson has contrived a bed, interrupted in the middle by a space one square metre in extent, unoccupied by any mattress; on each side of this space, towards the head and foot of the bed, is a mattress covered with macintosh. A deep tray is fitted to the iron sides of the bed, so as to lie under the open space, the tray is perforated by a large aperture through which the fluids may escape into a receptacle beneath. A stout iron bar bridges over the space, being fixed to the iron sides of the bed, along which it can slide upwards and downwards. In the middle of the bar is a raised portion, convex upwards and covered with a narrow macintosh pad or cushion. If a bubo has to be laid open, the couch is rolled alongside the patient's bed, and he is raised on to the couch, the bar over the space being slid under his nates, so that his sacrum rests on the elevated cushion. The sinus, when laid open, can be freely washed and syringed, the fluid running down the perineum or over the pelvis, by the flanks, into the tray under the space, and the integuments of the patient's back escape all contact with the fluid. The flanks and perineum can readily be dried. By a contrivance, the foot of the couch can be elevated or depressed, to place the patient in a convenient attitude for phimosis operations, or for any incisions in the perineum, where much blood is lost, and free washing with water or lotion is required.—*British Medical Journal*, September 30, 1882.

Digestion of Cane-sugar in the Human Stomach.—From experiments made on this subject, Leube (Virch. *Arch.* lxxxviii. 2, 1882) concludes that experiments which have heretofore been done were rendered untrustworthy by the fact that the sugar used was not of pure quality. He insists that the first requisite for the success of the experiment is the purity of the sugar used. It must be taken in the form of crystals. We must always subject the specimen to the sulphate-of-copper reduction test before using it. He experimented with the gastric juices of healthy and diseased stomachs, and finds that they act quite differently as to their effects on cane-sugar. Both possess the power of reducing cane-sugar, but their powers of absorbing the reduced product are not the same. The action of a healthy stomach on cane-sugar is almost nothing, but that of an unhealthy stomach is very strong. He came to the conclusion that: 1. The gastric juices of healthy stomachs, and those of some forms of diseased stomachs, have the power of reducing cane-sugar. 2. The reduced sugar after having been formed, is absorbed by a healthy stomach, but not always by a diseased stomach. 3. The acids of the gastric juices play an important *role* in reducing the sugar in the stomach.—*New York Med. Journ.*, Oct. 1882.

A Source of Error in the Examination of the Knee-phenomenon.—Prof. C. Westphal (*Arch. f. Psych. u. Nerv.*, Bd. xii.) calls attention to the fact that certain patients, in whom the knee-phenomenon has been positively absent for a long period, may exhibit at certain stages of the disease strong contraction of the quadriceps on percussing the patellar tendon.

Three cases are cited in which this occurred, persisting for a short time, and then disappearing. The author concludes that this is not a return of the tendon-phenomena, but is a skin reflex; for when a fold of the skin over the patellar tendon was lifted and squeezed between the fingers, contraction of the quadriceps followed; also pinching and percussing a fold of the skin in other parts of the leg may excite in some cases contraction limited to the quadriceps or extending to other muscles of the leg and thigh. There exists, he says, two independent phenomena: namely, a true, and a pseudo knee-phenomenon. It may be claimed that, as in tapping over the tendons, the skin

is necessarily excited; at the same time the presence of the true phenomenon in such a case could not be proven. Opposed to this are the facts that, in the first case (tendon-phenomena), the ordinary immediate and quick contraction follows percussion, while in the second (skin reflex), at least at first, a distinctly appreciable interval occurs. As a rule, also, stronger percussion is required to produce contraction in the latter than in the former case.

The author reports experiments made by himself and others to elucidate this nature of tendon-phenomena; in one of which, notwithstanding that sections of the fifth, sixth, and seven lumbar, and first sacral pairs of nerves were made, the knee-phenomenon remained completely preserved. He enters into a consideration of the question whether it is a true reflex or not. Although leaving the question undecided, he still favors his former view, that muscular tone and a certain degree of tension and vibratory power of the tendons are the only conditions necessary for the production of rhe tendon-phenomenon, the additional theory of a teflex process by means of centripetal nerves from tendons or muscles being unnecessary.—*Journal of Nervous and Mental Diseases*, July, 1882.

Burns of the Eyeball by Chemical Agents.—In speaking of this subject, Weinberg (*Rec. d'Ophthal.*, June, 1882) takes up first the subject of burns from acids. He finds the accidents caused by mineral acids generally more severe than those caused by metallic oxides, because being liquids they spread much more easily and cause more extensive accidents. The accidents caused by the contact of the conjunctiva with acids vary according to the degree of affinity which the latter have for water, and according to the extent of the surface of contact. When the agent is alkaline, as, for instance, quicklime, the results are much more grave. Immediately after its introduction into the eye, there is seen upon the conjunctiva a thick, white, adherent membrane, surrounded by a chemosis. Burns of the cornea are graver than those of the conjunctiva. When only the superficial layers are injured, the scar is white and transparent, but when the whole cornea is involved, it is hard, white, and opaque. Burns of the sclera are usually superficial, it being protected by the conjunctiva. As regards treatment, Weinberg advises first a careful removal from the eye of all trace of the chemical agent which may have entered it, and then dilution or neutralization of the agent, cold water syringing being the best means for this purpose, except in cases of burns by quicklime, where it should never be employed.—*New York Med. Journ.*, Oct. 1882.

Rupture of the Uterus.—Dr. R. H. Sabin presented a specimen of rupture of the uterus at a meeting of the Medical Society of the County of Albany. It had been thought to be a slough of the fundus resulting from inflammation, but was concluded to be a true rupture, extending across the entire fundus, with ragged edges, the adjacent parts being thinned. The uterus was the size of one at the third month of pregnancy; it presented no appearance of malignant deposit.

The subject, aged 46, was the mother of eight children, the youngest 4 years old. In August she complained of gastric irritation, but did not believe herself pregnant. Six weeks later she was taken with profuse flowing, for which she was given ergot, tannin locally and afterwards tamponed, checking the hemorrhage. No evidence of fœtal existence was found. She was much prostrated, and stimulants were given as freely as she could retain them. This was October 4th. On the 6th she was taken with severe pain across the lower part of the abdomen. She died the same day. Some time prior to the commencement of the hemorrhage she had been taken with bearing-down pain, for which another physician had prescribed. He found a polypus the size of a fig attached to the uterus, projecting from the vulva, which detached on the introduction of a sound; no hemorrhage followed, and she was gaining fair health up to the time when the flowing began. Autopsy showed the uterus as described. There was a little pus, but no blood in the peritoneal cavity.

It had been suggested that the case was one of extra-uterine pregnancy, the supposed polypus being a portion of membrana decidua, but this diagnosis was subsequently withdrawn by the author. On discussion, there was conclusion that a body of some sort must have been present within the womb before rupture occurred.—*Medical Annals*, September, 1882.

Convallaria Maialis.—M. Royer recommends the following formula for the administration of this drug:

Extract of *Convallaria maialis*,	q. s.
Simple syrup, . . .	100 grammes.
Tincture of sweet orange-peel,	5 "

This is said to make a very agreeable mixture, resembling syrup of bitter oranges.—*Bull. Gen. de Ther.*, Sept. 15, 1882,

The Base and Acid Relations of the Serum of the Blood and other Animal Fluids, and their Relation to the Formation of Secretions.—Prof. Maly (*Wien. med. Woch.*, July 1, 8, 1882) concludes a paper on this subject with the following deductions: 1. In spite of the alkaline reaction of the blood, it contains salts of an acid reaction, such as the monophosphate of sodium (NaH_2PO_4), which forms when the diphosphate of sodium and carbonic acid come in contact. 2. That such alkaline-reacting substances as diphosphate of sodium and bicarbonate of sodium are, theoretically, acids, since they contain an intact hydroxl which is capable of being replaced by a metal. 3. Both organic and inorganic acids are continually formed in the blood by oxidation, such as carbonic acid, sulphuric acid, phosphoric acid, and such intermediate acids as hippuric acid, uric acid, etc. 4. The changes between the acids and bases in the blood are highly complicated, as they are in other fluids, and, although the reaction of the blood is alkaline, there are many compounds of it which are of an essentially acid nature. Alkaline substances are to be found in the blood only in an empirical sense, while, theoretically, alkaline substances are not to be found there, nor indeed is it possible for them to exist in it. 5. The acids and acid salts of the blood are much more diffusible than the neutral substances, and therefore in such a mixture of salts and acids as we find in the blood, the acid molecules are more diffused. This he concludes to be very important in the formation of acid secretions by the various glands of the body. He then gives the chemical formulæ for the various transformations in the body. He concludes by saying that, since the blood brings about acid reactions, it must be acid itself. He then raises the question, What part of it produces these acid reactions? He thinks that there are many acid parts of it; that the acid substances are very minute, but are in a free state. The stronger the acid, the less of it is free, and the more of it combines with salts; the principal free acid is carbonic acid, because it is the weakest, and the only one in a gaseous form. The action of these acids is expended on all mineral and organic substances which can combine as bases, from carbonic acid to the albuminous molecules. From these causes the digestive substance, peptone or propeptone, has an acid reaction, as he promises to show in a future publication.—*New York Medical Journal*, October, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in registered letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, OCTOBER 21, 1882.

THE RELATION OF THE MENTAL STATE TO THE CRIMINAL RESPONSIBILITY OF SUPPOSED LUNATICS.

In the issue of the *Journal of Nervous and Mental Diseases* for July, 1882, which has just reached us, The Medical News is severely criticised because it ventures to hold opinions at variance with certain New York neurologists, including the editor of the journal above referred to. There are two counts in the indictment. One is that The News adheres to the legal definition of responsibility; the other, that it indulges in "cant," and is "unscientific." The last two expressions are used to designate the character of an editorial as compared with a paper in a local journal, in which Guiteau is solemnly affirmed to be possessed of an "affective or moral insanity"—in other words, of the form of monomania entitled "reasoning mania," or the euphemistic *primäre Verrücktheit.* We are quite willing to be separated by a broad line of demarcation from this group of mental philosophers.

With the view to render our own position clear, and at the same time to demonstrate its consistency, we must recall a few points in the Guiteau literature. Guiteau was an eccentric, who, to a singular religious training, added an incomplete education as a lawyer. As is the case with the class of "deadbeats" in general, who to a man are indisposed to steady employment, he resolved to get his living by his wits as so many of his predecessors had done. To be put into some lucrative position, where the pay is large and the duties merely nominal, was the special object of his ambition. Seeing no prospect of such a consummation from the administration then in power, he began to reflect on the important position he must occupy if he should "remove the President." No lawyer within his experience had been convicted of the vulgar crime of murder. A maniacal impulse had been, within the range of his own observation, admitted as a cause of crime, for which no punishment but temporary incarceration in an insane asylum had been inflicted. "Transitory mania," "insane impulse," and similar terms, had, in various celebrated criminal trials, been all-powerful in securing acquittal. He therefore concluded that, as a lawyer, these pleas would be sufficient with court and jury, and that although remanded to an insane asylum, there would be no difficulty in a short time in re-establishing his sanity—in proving his recovery from transitory mania. After an experience of this kind, there was no question in his mind, he would be adequately rewarded for his sacrifices by the new administration. Such, doubtless, was the process of ratiocination by which this poor wretch arrived at his determination to perpetrate the crime.

The question of Guiteau's responsibility rests entirely on the question whether he possessed sufficient power of will to restrain him from the commission of a crime which he considered would advance his interests. The successive determinations, and withdrawals from them, by which he advanced to the crime, show that if he had not had a sure conviction of his acquittal he would finally have decided not to attempt the murder. Having thus a clear conception of the nature and consequences of his act and sufficient will to restrain his inclination to commit the crime, we hold that he was a responsible being before the law.

We have, also, distinctly recognized the fact that Guiteau was not a normal person. He had the characteristics of the criminal class to which he belonged by right of birth and through the influences of a faulty education. The criminal class is abnormal. They have a mental structure whose manifestations are toward vice in its various forms, and a bodily conformation which corresponds. They are inferior, mentally and physically to the average type of the community in which they have their origin. They have misshapen heads, poor chests, and weak muscles, as a rule, and in their mental make-up, the appetites and passions dominate the reason and judgment. As respects their inclinations, they have little power of will over their actions, and when an object is much desired, their reason is powerless over the means intended to accomplish the end. Such was Guiteau. To assume that an abnormal individual of such a type, is not amenable to the ordinary responsibilities for human conduct, is to exempt the great body of the criminal class from punishment for their crimes.

Guiteau had the expansive ideas of a subject of dementia paralytica, but his schemes were not un-

reasonable. The establishment of such a paper as he proposed in Chicago, was not a chimerical scheme like running a railroad to the moon. Indeed, the best informed on this subject agree that his plan had the elements of success in it, if rightly carried out. As respects his other schemes, there was no inherent improbability in the purposes which he had in view. Contact with politicians had, doubtless, taught him how inferior in every respect were the men who had attained to high station. That he should entertain an ambitious project of this kind, was surely no evidence of delusion of the expansive type, characteristic of dementia paralytica. There was, therefore, nothing in the conduct and condition of Guiteau to separate him from the criminal class to which he belonged by inheritance of a faulty organization, and by education. He was one of them, to be judged accordingly, and not to be compared with the average type of normal human kind.

Much stress is laid on the microscopical appearances of Guiteau's brain. The gross structure did not depart in any material way from the ordinary type. Cerebral topography has not yet attained the dignity of an exact science, and hence the attempt to give importance to particular convolutions, as described by unknown experts, is not fortunate. The changes unearthed by the microscope are more important. The view of THE NEWS, in the editorial which accompanied the details of the microscopical examination, has been generally adopted, and is the view maintained in an editorial in the July number of the *Journal of Nervous and Mental Diseases*, just issued.

The initial lesions of dementia paralytica are those described in the record of the microscopical examination. How long did these exist? It must be remembered that Guiteau was an individual of the neurotic type. Now it is obvious, that the lesions of evidently recent occurrence owed their existence to the deterioration of health produced by the confinement in jail and the excitement incident to the trial. They are too recent and restricted to be referred to the period when the abnormalities of his life began to be manifest. If to these changes of the organic substratum is to be referred the impulse leading to the murder of the President, all other eccentricities of his life must also be explained by them.

THE NEWS was also criticised because it maintained the judicious doctrine that conclusions should not be reached from a mere study of *post-mortem* appearances—that the clinical history must be studied in connection with the alterations of the organic substratum. It is surprising that such a statement should require vindication. Who does not know that extensive disease of the brain may co-exist with a normal state of the intellectual functions, and that mania may not be accompanied by any recognizable evidences of cerebral disease? The late Dr. J. Hughes Bennett, for example, was found after death to have a tumor of the brain involving the cortex, and it was not alleged that he suffered from some form of mental derangement. So obvious, indeed, is the accuracy and applicability of this statement that it would be a waste of time to adduce arguments and facts in its support.

We must regard it as a fortunate circumstance that right views prevailed at last on the Guiteau trial. If the opinions of the experts for the defence had decided the contest, the most hopeless criminal might plume himself on the doctrine of irresponsibility based on the paralysis of his will. He might have a perfectly just conception of the nature of the crime and of the punishment awarded by the laws, but if he could secure experts to prove that he committed a crime because he had an insane impulse, and his will was overpowered, he might look forward to acquittal as an irresponsible lunatic.

MERCURY IN SYPHILIS.

IT is astonishing how firmly rooted and almost ineradicable a popular prejudice against any particular drug, or even against any special system of medication, becomes if judiciously fostered and encouraged. The persons who appeal to public sentiment in medical matters are usually quacks or fanatics, often ignorant, and generally unscrupulous, but by dint of constant repetition, and by generalizing from isolated and exceptional cases, and by assuming that errors once common in the profession, but long since outgrown and discarded, are still of frequent occurrence, they rarely fail to secure a zealous and numerically respectable following. Homœopathy owes most, if not all its successes, to the reaction which has taken place against the excessive dosing of the last century, and which, originating in the wider observation, and more scientific methods of modern medicine, has been sagaciously, though dishonestly, appropriated by the Hahnemannians. The anti-vaccinationists derive their only shadow of reasonable support from a few isolated and dubious cases of unpleasant sequelæ, the result of ignorance or carelessness. The indiscriminate bloodletting of our predecessors, while it unquestionably shortened many lives, has doubtless caused the loss of not a few by producing the almost total abandonment of this powerful and, when rightly applied, beneficial therapeutic measure. And in the same manner, the inordinate use of mercury, with the unnecessary production of salivation and other toxic effects of the drug, has resulted in a prejudice against it, which, nursed by homœopaths, herbalists, and advertising quacks, has survived to the present day,

and is encountered almost constantly by the practitioner.

This prejudice probably does more harm among those members of the lower social stratum who are unfortunate enough to contract syphilis, than among any other class of the community. Not accustomed by training or education to depend upon the dictum of an intelligent family physician, too poor to seek specialists, and imbued with the idea above mentioned, derived usually from the columns of the daily papers, they either fall victims to the counter-prescribing druggist, who, even if he by chance recognizes their ailment, yields readily to their request for some "vegetable" preparation, or else they are robbed and maltreated by the charlatan whose announcement of "no mercury" has happened to attract them.

All this is bad enough, and can only be remedied by the greater diffusion of knowledge among the lower classes, and by more stringent legislation, which will protect them in their ignorance against these and other unauthorized or incompetent practitioners. Unfortunately, however, this same prejudice is sometimes encountered within the ranks of our profession, and among physicians who should be better informed. It is quite time that every medical man who assumes the charge of a case of syphilis should be aware that statistics derived from a careful observation of thousands of cases, and from an impartial comparison of results obtained by different methods, show conclusively that the chief if not the only chance a syphilitic patient has of complete recovery depends upon the intelligent employment of some form of mercury, during a more or less protracted period. Perhaps no therapeutic fact is better established, certainly none is more important in its bearing on the general welfare.

The reason just mentioned—the overwhelming clinical evidence in favor of the usefulness of the drug, both in the control of the early symptoms and the prevention of later developments—is sufficient for its employment, but there are equally good theoretical reasons. The discussion of these we shall reserve for a future article, contenting ourselves for the present with reiterating the fact that, whether mercury acts as a true tonic in syphilis, directly increasing the number of the red blood cells, or as a physiological antidote of some subtle poison which it destroys, or by means of its power in promoting destructive metamorphosis and fatty degeneration, thus hastening the removal of accumulated cell products, it is unquestionable, first, that it does good, and that syphilitics to whom it has been properly administered do far better than under any other known plan of treatment; and, second, that the physician who prescribes it is not choosing the least objectionable horn of a dilemma, but is employing the most rational and scientific method known to the profession for the relief of one of the most terrible and destructive maladies.

THE SOURCE OF THE VACCINE DISEASE.

The statement made in these columns, based on the reports of Gassner, Ceely, Badcock, Putnam, of Boston, and others, that the vaccine disease, as it occurs in heifers, is modified variola has been warmly disputed. Such was the original view of Jenner, and such has been the experience of Jenner's immediate followers. Some unfortunate inoculations of variolous matter, by Dr. Martin, of Boston, and similar experiences elsewhere, threw doubts on Jenner's doctrine. Furthermore, Jenner's doctrine has been strongly opposed by Chauveau, of Lyons, Bollinger, of Germany, and Fleming, of England, who have maintained that spontaneous cowpox is a different malady from human variola. Some new observations by Dr. Voigt, of Hamburg, have resolved the doubts and re-established Jenner's authority.

As Superintendent of the Vaccine Institute, Dr. Voigt may be supposed to have some acquaintance with the subject of vaccinia, and to be able to reason aright from the simple experimental data which he has obtained. For an account of these investigations we are indebted to our contemporary, *The Medical Times and Gazette* of Sept. 23, 1882. Voigt's experiments reconcile the contradictions involved in such trials as Martin's, whose inoculations of variolous matter produced only smallpox, and the trials of Ceely, which, after much painstaking experimentation, finally produced the true vaccinia. Voigt has demonstrated that true variolous matter must be passed through at least six animals to be properly transmuted. That which is obtained by the first inoculation has all the activity nearly of the original variolous matter, but by successive transmissions through the system of the cow such a reduction in the activity of the poison (virus) is effected that the results of its inoculation correspond to those of the spontaneous vaccinia so-called. The behavior of this vaccinia corresponds to the action of the variolous poison as modified from vaccination. It is known to all the world that some cases of varioloid possess a virulence closely approximating variola, whilst others are so far modified and lessened in activity that they are scarcely ill. Now, it is obvious that the infection of heifers will have a corresponding activity. Some will have a degree of virulence closely approximating true variola, and others will have the mildness of vaccinia.

It thus happens that the researches of Voigt have supplied us with the needed data. We are now able to reaffirm the orignal position of Jenner, and

maintain that vaccinia is a modified variola—modified by transmission through the system of the cow. If true variola is inoculated, the product is but slightly inferior in activity to the original variolous poison; but by successive transmissions the virulence is gradually abated, until it attains the properties of vaccinia. If modified variolous poison is inoculated in the heifer, the product has a corresponding activity. Thus by the timely selection of the matter inoculated we can regulate the virulence to suit the conditions to be provided against. In the future we ought to be furnished with vaccine having the degree of activity just necessary to our purpose.

THE CURE OF DIABETES WITH BROMIDE OF POTASSIUM.

M. FELIZET asserts that he has a record of five cases of diabetes cured by the administration of bromide of potassium. Holding the view originally expressed by Claude Bernard, that diabetes is produced by irritation of the floor of the fourth ventricle, he used bromides to remove this morbid condition. He finds that the local irritation is arrested and the disease cured by the administration of the bromide of potassium. The cure is effected, quite irrespective of dietetic regulations, by the effect of the agent on the medulla. However, large doses kept up for a long time are necessary to effect the curative result.

On this side of the Atlantic the bromides have long been used in the treatment of diabetes. We do not know of any reports which can exhibit equal results to those achieved by Felizet. Have the doses administered been too small, not persevered in sufficiently, or given in cases too far advanced to permit repair? These are questions which will require a large number of carefully observed cases, to answer with certainty.

LIFE INSURANCE FOR MEDICAL MEN.

IF, as we believe, life insurance is a wise provision for most men, for doctors it is especially wise. Life, which is uncertain at the best, is peculiarly uncertain for our profession from its very nature. If he whose house burns down uninsured is accounted careless, how much more should he be whose life is suddenly terminated without any provision for the future; and with this difference in favor of life insurance, that everybody must die, but not everybody's house must burn down.

Moreover very few doctors ever accumulate a fortune. With ordinary ability and ordinary faithfulness, a doctor is sure to obtain an income which will give him and his family a good support, an income which is almost as certain as a salary. But it is rarely large enough for him to lay by any considerable sum from year to year. If he live to old age, or if his income be exceptional, or if he engage successfully in other business or in speculation, he may become rich. But it is expressly to provide against the possibility of poverty following early death, or failure in business or speculation, that life insurance is valuable. As medical examiners, a very large number of the profession are familiar with the wisdom of insurance, and with signal instances of its benefits. As a rule, the medical examiners are, we believe, insured, as indeed consistency would require. But we fear that only a small percentage of the remainder of the profession have so provided for their families.

It is often objected that life insurance is so uncertain that the risk of dying early is less than the risk of losing all one's investments. But after a careful survey of all the life insurance companies in this country, the *Ledger* has shown that only about one per cent. of all the insurances effected have been lost, whether through the ordinary casualties of business, bad judgment, fraud, theft, etc., all combined—a percentage less, we imagine, than that which is true of most other forms of business, and, of course, in recommending insurance, we take it for granted that the insured will use proper wisdom and only invest in well-established companies whose strength is a guarantee of payment in, it may be, a far distant future.

WHILE we heartily advocate athletic sports among college men, we are glad to see that the Harvard College authorities are about to undertake the regulation of this matter of physical exercise, in order to give it its due development, but yet not to allow it to encroach on the studies of the college course; that is to say, the proper business of the young men.

They propose to limit the students to athletic sports as amateurs and not as "professionals," a position they have been rapidly drifting into of late. With the assistance of the faculties of other colleges they propose, therefore, to prohibit their baseball clubs from playing with professional clubs. They will retain the present excellent supervision of the gymnasium which Dr. Sargent exercises, and will add to it some one to see that the students take proper care of themselves in their sports and that they do not go to excess. This latter person will take the place of the professional college "trainer," whom they have dismissed.

The Yale faculty, however, have declined to join Harvard as to the baseball nines.

OUR esteemed contemporary, the *Lancet*, we notice, in quoting from our columns lately, transforms our friend, Dr. Formad, into Dr. Furniss, and still more curiously adds a monarchial halo to our staid old College of Physicians by an allusion to the *Royal* College of Physicians of Philadelphia.

REVIEWS.

A System of Human Anatomy, Including its Medical and Surgical Relations. By Harrison Allen, M.D. With 109 plates and 250 wood-cuts, drawn by Herman Faber. Section I., Histology, by E. O. Shakespeare, M.D. Section II., Bones and Joints. 4to. pp. 241. Philadelphia: H. C. Lea's Son & Co., 1882.

A book like this is an ideal rarely realized. It will do, we have no doubt, what its accomplished author hopes, "make anatomy—what unfortunately it rarely is—an *interesting study*." Dry bones are of the driest when merely the bare facts about them are stated. But the value of anatomy to the medical man as distinguished from the scientist, like that of an observation, "lies in the application."

The "sauce piquante" which whets the appetite, is found in the explanation which anatomy gives of the facts of disease in its clinical relations.

It has long been an opprobrium to America that our anatomical text-books were all foreign. But this work will remove the stigma. It is a mine of wealth in the information it gives. It differs from all preceding anatomies in its scope, and is, we believe, a vast improvement upon them all. While the anatomical descriptions are full, they are not prolix, and they avoid many of the details which, though of scientific value, are worthless to the doctor. Yet the variations of the parts will be sufficiently described. But the chief novelty about the book, and really one of the greatest needs in anatomy, is the extension of the text to cover not only anatomical descriptions, but the uses of anatomy in studying disease. This is attained both by stating the narrower topographical relations and also the wider clinical relations of more remote parts, by giving a brief account of the uses of the various organs; and by quoting cases which illustrate the "localization of diseased action." In future parts there will be sections on monstrosities, on the method of conducting *post-mortem* examinations, and on superficial anatomy as a guide to the positon of the deeper parts.

Dr. Shakespeare has furnished the section on histology, and it is well done. We regret however, to see nearly all the illustrations are copies, and that the magnifying power, instead of being stated exactly, is indefinitely described as "high," "low," or "medium."

We have not space to enter into any details of the section on the bones and joints. Suffice it to say that it shows on every page evidences of Dr. Allen's wide learning and judicious selection of material, embarrassing by its very richness. The style is in general succinct and clear, but sometimes from its brevity it lacks clearness, as in part of the description of the movements of the elbow-joint. We regret to observe the use of "diagnose," for "diagnosticate," which is the proper, and indeed the only proper, English word.

Second editions can only be corrected by the discovery of faults in the first. Hence we take the liberty to point out a few minor errors. Thus on page 114, Holmes Coote's name, and on page 140 Dr. Mütter's, are mispelled, and so on page 230 with Gemelli. On page 117 the coronoid process of the ulna becomes coracoid. On page 149 the last two words of the last paragraph are incorrect. In Plate XXXIII., while it is not incorrect to print the name gastroc-nemius, it would have suggested its Greek origin much better had it been gastrocnemius. So too in the text the foramina of the sphenoid bone are called by their English names, while in the plates the Latin are used, a confusing thing to a beginner. The foramen spinosum is not shown in the plate.

But these are such small faults in so fine a work that we scarcely would dare to call the author's attention to them, were it not that we wish it the greatest possible success, and, therefore, the greatest possible perfection.

The plates are beautiful specimens of work by one who long since won a deserved reputation as an artist.

SOCIETY PROCEEDINGS.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, October 4, 1882.

W. S. W. Ruschenberger, M.D., President, in the Chair.

Dr. Arthur V. Meigs read a paper entitled

CLINICAL OBSERVATIONS ON ALBUMINURIA, BASED UPON A STUDY OF SIXTY-TWO CASES SEEN IN PRIVATE PRACTICE.[1]

During the last eight or nine years, he said, it has been my habit to keep a record of the examinations of urine I have made. That record now contains notes of between sixteen and seventeen hundred examinations, and a study of it recalls to my mind, with more or less distinctness, the histories of sixty-two persons suffering with albuminuria. In a number of instances I have been able to follow cases for a series of years, from this circumstance. In particular, the number of years the patients were under observation, I have been enabled to satisfy myself of some clinical facts, particularly in reference to the diagnosis and prognosis in this complaint, which I hope may be worthy of your attention.

That which has most impressed me, is the impossibility of making a prognosis, with any degree of exactitude in most cases of Bright's disease. Of course, in the plainer ones, the decision is easy; if asked an opinion in a case with a large; or even moderate amount, of albumen in the urine, with increasing heart failure, and evident decline of strength and vitality, with headaches and the peculiar white complexion of the disease, it is easy to prophecy that such a person will not live long, and the prophecy, nine times in ten, comes true; if called, however, to decide questions of the future for a young man of thirty-two or three, previously well, but for some weeks complaining of headaches, malaise, and boils, and then examination of the urine shows a slight amount of albumen, granular and hyaline casts, and abundance of rather small oxalates, the question of the future is not so easily decided. I have seen such cases go on pretty well for a few months, then suddenly have convulsions, and die in a few days. Again, persons presenting identical symptoms, after being sick a few weeks or months, entirely recover. To my mind it is impossible, in the present state of our knowledge, to anticipate the future, and the patient should always have the benefit of the doubt, and be shown the brighter, rather than the darker side of the picture.

I know of three persons in whose urine I found albumen and tube-casts, accompanied with all the other signs of Bright's disease more than eight years ago, who are yet alive. One is a lawyer in easy circumstances, who was taken sick in January, 1874, when he was fifty-six years of age, with what appeared to be a bad cold, but he had extreme dyspnœa and exces-

[1] Many of these cases occurred in the practice of my father, Dr. J. Forsyth Meigs, but a large majority of them I saw from time to time myself.

sive restlessness and nervousness, although he is usually very self-composed. The dyspnœa seemed greater than could be accounted for by the extent of disease of the lungs, which amounted only to moderate bronchitis; the urine being examined, it was found to contain a trace of albumen, some blood, and tube casts. It should be said that this man had suffered in previous years with attacks of gravel,, when he would pass blood, and small calculi. Nearly four years afterwards, there was still a trace of albumen in the urine, and granular casts, showing that the condition was by no means merely temporary. Ever since, he is liable to severe cold, and always suffers more than common with oppression, although it usually takes the form of a common coryza. He is now sixty-four years old and an unusually young-looking, active man of his years.

In contrast with this case, a woman of about sixty was seized in the night, having gone to bed apparently in her usual health, with an attack of oppression, and what her physician called congestion of the lungs, so violent that it was thought she would die at once; she, however, rallied by morning. An examination of the urine, made a few days afterwards, revealed the presence of a slight trace of albumen and casts. Four months afterwards there was still a trace of albumen in the urine, and granular and fatty casts, although she was up and about as usual, being merely very weak, having no apparently urgent renal symptoms. At a later examination, the trace of albumen was still found, but no casts. About seven months from the first discovery of the disease, she had another violent attack of oppression, and died in a few hours. Now what are the points to distinguish these two cases? One died after a few months' illness, and the other, having had apparently the same complaint and almost identical symptoms, is, after eight years and a half, still alive, and more, apparently unusually well for his time of life.

In December, 1874, a lawyer in full practice, then about fifty-four years of age, was taken with an attack of acute catarrhal pneumonia, and was also found to have albumen and tube-casts in the urine. He was sick all that winter and the following spring, the urine constantly containing albumen, and granular and hyaline casts. The albumen and casts were found in the urine during 1875 and 1876, and part of 1877. On May 2, 1877, about two and a half years from the onset of the disease, there was at last no albumen found, and the microscope revealed nothing abnormal. Since that time, although the urine was examined in 1878, 1880, 1881, and 1882, there has never been found either albumen or tube-casts, and the patient, now a man sixty-five years of age, enjoys very good health, having had no return of the disease in more than five years.

The third case is a woman, whose father, brother, and two sisters have died of the same disease. She has had a trace of albumen and hyaline and granular casts in her urine since March, 1874, when she was about thirty-one years of age. I have records of this condition in 1874, 1876, 1879, 1880, 1881, 1882. In February last she caught cold, and seemed for some time upon the verge of a severe renal attack, having coryza so that her nose was almost entirely stopped, and there were bronchial râles heard in the chest, but an amount of dyspnœa seemingly out of all proportion to the extent of the disease that could be detected by physical exploration; the albumen in the urine also increased very much in quantity In some weeks, however, she recovered, and this summer seemed in her usual health.

The father of this patient had a severe attack of hepatic colic, and passed several gall-stones in 1877, but afterwards he continued in pretty fair health for some time. On May 9, 1879, a trace of albumen was found in the urine; this continued to be present at succeeding examinations, but no tube-casts were found at this time, or afterwards, although they were carefully sought for, and about December, 1880, eighteen months from the original discovery of his disease, he succumbed to an attack of uræmic convulsions, being seventy years of age. A son and two daughters of this man died of the same disease some years before. The son, after having had dropsy, lived for several years in tolerable comfort, until a severe cold proved fatal. With the history of this son, and one of the daughters, I am not familiar, but the third one I saw, and she died in convulsions. The condition of this person before her final illness, which lasted only a few days, was in no way different from that of her sister, who is still living, and has had the disease for nearly nine years, and the attack which the surviving one had last March, was exactly like those of which I have seen other people die.

I maintain, therefore, that with our present knowledge it is impossible, in doubtful cases, to prognosticate what the result will be, and that for the patient and his family, as well as for the credit of our profession, we should be very guarded in our prognosis. The presence of albumen and tube-casts in the urine, even when found for so long a time as two years continually, is not, as shown by one of the histories I have detailed, a reason why we should necessarily give a fatal prognosis, and this is particularly the case when the patient is a person past middle life. In the face of such authorities as Beale and Grainger Stewart, many practitioners think the microscopists can better judge (by examining the urine) of the stage and form of Bright's disease they have to deal with than they themselves can. Grainger Stewart is emphatic upon this subject. On page 271 of the American edition of his work on *Bright's Disease*, he says: "Some authors attach great importance to the tube-casts. They are of undoubted value in establishing the existence of Bright's disease, considered generically, but they afford comparatively little assistance in the differential diagnosis of the different forms. Any form of tube-cast may occur in any form of the disease, and at almost any stage. Indeed, all the leading varieties may occur simultaneously in one case." Beale says (*Kidney Diseases, Urinary Deposits, and Calculus Disorders*): "Dr. Basham thinks he can judge of the stage of Bright's disease by the character of the urinary sediment. I wish I could agree with him in this conclusion. The more carefully the matter is investigated the more convinced am I that it is unsafe in many cases to attempt to draw inferences as to the stage of the disease from the character of the urinary sediment only. Nothing but a careful consideration of every point connected with the case will enable us to arrive at a general conclusion concerning the state of the disease. . . . Dr. Basham says: 'The most untractable and hopeless form of *morbus Brightii* is that represented by the presence of the fatty or oily cast.' This statement requires some qualification, for although it is quite true that some of these cases are terribly and rapidly fatal, it must be admitted that some live for twenty years and more and die at last of other disorders." With regard to the presence of oily casts in the urine, and it is upon their discovery that microscopists found their gravest prognosis, Dr. George Johnson says (*Lectures on Bright's Disease*, New York, 1874): "The appearance of oily casts and cells excites less alarm now than it formerly did. It indicates that in certain parts of the kidney the secreting cells and inflammatory exudations are undergoing fatty transformation; but I have seen many cases of complete recovery after oily casts and cells in great numbers had appeared in the urine continuously for many weeks."

A very common symptom of renal disease, and one upon which there is not very much stress laid in the majority of books upon the subject, is dyspnœa. Whenever a patient is found suffering with dyspnœa, and particularly if there is great nervousness, and loss of self-control, and anxiety, with no other fully sufficient cause for its existence, suspicion of renal disease should be aroused, and the urine examined, even if there are no other symptoms whatever pointing toward a lesion of the kidney. These attacks of dyspnœa frequently come on with great suddenness in persons who have not considered themselves sick, and such attacks are often quite rapidly fatal. This condition has been described as renal asthma, but I believe it much more common than is usually supposed. Another symptom of Bright's disease which I have frequently noticed and have never heard described, is coryza, of such a character that it gives rise to very much greater distress than any ordinary cold in the head; with this there is not much discharge from the nose, but the patient complains that he can get little or no air, except through the mouth, this being accompanied with excessive oppression, much more than the condition would seem to warrant. This symptom was first called to my attention by my father, Dr. J. Forsyth Meigs, in a case we saw together, about nine years ago.

The suddenness of the onset, or perhaps it would be more correct to say, of the discovery of the existence of this disease, is often very great. In one instance, I knew of a young man, previously supposed healthy, seized with a convulsion while sitting at the supper table, after he had finished his day's labor as a wagon-driver; this was followed by others, and the case ended fatally in a few days. In a second case, I was called upon by a young woman to explain a swelling of the vulva, with which she was suffering; examination of the urine revealed the existence of a large amount of albumen; this continued for some time, but after prolonged use of iron, her condition improved, and she had apparently fair health, until about two years later she became pregnant, and died within a few days after the birth of her child. In a third case, a man, fifty-four years of age, was seized in the night with epistaxis, a thing he had not had since he was a boy; examination of the urine revealed the cause, and about six weeks later he was found one morning insensible in the bath-tub; examination showed that he had right hemiplegia; a vessel in the brain had ruptured, presumably from the same degeneration which six weeks earlier had caused the nose to bleed. On the other hand, the insidious nature of this disease and of its onset is a matter of such common report that I will not weary you with any cases illustrative of this fact.

The existence of oxaluria, or of uric acid lithiasis, is a prolific source of mischief to the kidney. The deposit of oxalates, or uric acid in the kidney, and its passage outwards, occurs most frequently in persons who are large eaters, living an inert life and taking but little exercise. Such people are common among the rich in large cities, and I have seldom failed to find tube-casts in the urine of any one who passed gravel for any length of time, whether oxalates, or uric acid, even if the calculi were microscopic in size, and this, commonly before any albumen was to be found. Later, if there is any considerable amount of gravel passed, albumen and blood will be found in the urine. If the attacks of gravel occur often, they are apt, at last, to be followed by Bright's disease, directly caused, probably, by the mechanical irritation of the lining membrane of the tubules of the kidney, by the sharp edges of the minute calculi passing through them.

It cannot be proved by statistics, and yet I think there is strong ground for believing, that the proportion of deaths caused by affections of the kidney is greatly on the increase. The tendency of modern life seems to be such, that a larger number of deaths are caused by degenerative processes, and less by acute disorders. In former times, children were less delicately reared, and a larger proportion of the frailer ones probably died of exposure and want of care; now, beginning at childhood and continuing up to old age, we are much more careful to avoid exposure, and are more self-indulgent, at least, as far as our bodies are concerned. Who, in modern times, except the professional athletes, would undertake the physical labors of the Emperor Charles V. of Germany, of whom Motley says, that he was able to tell, at a time when all journeys were made on horseback or by boat, "of his nine expeditions into Germany, six to Spain, seven to Italy, four to France, ten to the Netherlands, two to England, as many to Africa, and of his eleven voyages by sea!" Nowadays the majority of city men are in their places of business all day, and take but little exercise, eating as much, and as rich food, as in former times, and drinking not little withal. The natural and necessary consequence follows, that after years of this kind of life, the excretory organs degenerate; first the kidney, which is the common sewer of the body, and, like the heart, has to do continual work, from the hour of birth until the hour of death. It is a common thing in modern life to see a man naturally robust and gifted with a large appetite, become more inert as years go by, when he will gradually give up his active exercise, until finally he takes none; still the eating and drinking go on, and he becomes fat and sluggish; finally he loses health, and then examination shows that degeneration is beginning in the kidney. I could instance several cases of the kind but my space will not allow me.

The drift of my paper has been to try to establish, that we should, in all ordinary cases of albuminuria, be very guarded in our prognosis, except when it is self-evident that the case must be rapidly fatal. I have now under my observation, fifteen persons, seventeen, if I count two who have albuminuria alternating or parallel with, diabetes mellitus, who have been suffering with this complaint for a greater or less length of time. With three of them, the disease began nearly nine years ago, and they either have it now, or have entirely recovered from it, after more than two years continual duration; yet in regard to no one of them do I feel able, even in my own mind, to guess, much less to formulate an opinion, as to how much longer they may live. There are absolutely no data, if such cases are considered in the light of the experience of the sixty-two I shall mention, upon which to found a positive prognosis.

Another observation I have made, is in regard to the deaths of very old people. We are all agreed I presume, that when a very old person dies, and we report the death as one of old age, it is because we are unable to put the finger upon the exact part of the old and worn out machinery, that at last refuses to work any longer, and thereby causes all the rest of the mechanism to stop. This direct cause, if sought for, will frequently be found in the kidney. To examine the urine is not always a thing that strikes us, particularly when absolutely no symptoms appear to point toward kidney disease. I have seen a number of instances, in which old people seemed to be fading out, as they often do, yet have felt entirely unable to explain to myself any direct cause for the failure, until the urine was examined, when there was found albumen, with granular and hyaline casts, and sometimes a few blood corpuscles. A careful inquiry would perhaps reveal the fact, that the amount of urine passed was very small, all this without any other symptom to point toward kidney disease; at the same time, the failure of the patient being very gentle and gradual;

or else, as not infrequently has happened, senile delirium existed, either violent or mild in type, followed at last by death.

In the whole sixty-two cases, which I will now summarize collectively, there have occurred twenty-six deaths, thirty-four are to my knowledge still living, some in better and some in worse health, and of two I have lost sight.

Five were cases of ordinary acute desquamative nephritis, with the occurrence of one death, and four recoveries. In one instance, a child, there were two attacks, two years apart, the first being unaccounted for, the second following scarlet fever; the second case occurred after scarlet fever; the third after diphtheria; the fourth was in a young man apparently healthy previously, and now in good health, his attack only lasted a short time; the fifth and fatal case was in a boy of about fifteen years of age, and came on while he was at boarding school, the onset being insidious, and the disease progressing from bad to worse, until death occurred.

Four cases seemed to be caused by the passing of gravel, principally oxalates. These people are still all living, although they have had albumen and casts present in the urine, on and off, for varying lengths of time; two of them for six years past, one for seven years, and the fourth has had two attacks of nephritic colic, about a year apart; on each occasion, albumen and granular casts, uric acid, and blood corpuscles were found in the urine.

Twenty-two cases I class as of ordinary Bright's disease, there being probably contracted kidney in the majority of instances, and of them, fourteen are dead. I made no post-mortem examination in any one of these cases. In most of them (seventeen of the twenty-two) the onset was insidious, there being no illness to mark the beginning of the disease; in one, the patient was seized with a convulsion at the supper-table, having been supposed previously to be in good health; in a second, there was a violent attack of congestion of the lungs, with terrible dyspnœa during the night, the patient, a woman, having gone to bed thinking herself in good health; in a third, there were dyspnœa and congestion of the lungs occurring suddenly; in a fourth the condition of the kidneys was discovered concurrently with an attack of catarrhal pneumonia; a fifth was a man who had had attacks of nephritic colic. He had a violent attack of congestion of the lungs, with bronchitis and dyspnœa, and was found to have albumen and casts in the urine, which condition continued, on and off, for four years; he is now in apparently good health, although the first attack was nearly nine years ago. Of these twenty-two cases, two were in one family, one soon dying, and of the other, I have lost sight; two in another family, one dying and the other, I think, being still alive, although the disease was discovered three years ago; five cases occurred in another family, the father, son, and three daughters. The father and mother of this family had ten living children, five reaching adult life, one died of consumption, and the other three, and the father, of Bright's disease, the surviving daughter has had the disease for nearly nine years. In another family there were three cases, all women; one died, having had uræmic convulsions, and the other two still live, both having had the disease for about three years. A brother has now cancer of the rectum. The mother is still alive, and although seventy-four, enjoys good health. The father died at quite an advanced age, but I do not know of what disease.

The next twenty-two cases I must classify as unaccountable; eighteen of them occurred in persons over sixty years of age, and the other four were well on in life; one was over ninety, three over eighty, and two over seventy years of age. Of these people, only five are dead, and of the five fatal cases, one was the man over ninety, two were over eighty, a fourth was seventy-seven, and the fifth sixty-seven.

The next four cases were of people advanced in life, and they died of general break-down, having in three instances concurrent disease of the heart and kidneys, with implication of the lungs, and the fourth had renal and brain disease.

In two instances there has been albuminuria with diabetes mellitus; in one sugar was discovered in the urine six, and in the other four, years ago. Since then, there has been sometimes sugar, and at others albumen; at times both at once in the urine of these two women. In neither instance have tube-casts been found. I mention these two cases in a paper upon albuminuria, because both have frequently had albumen in the urine, and I confess myself unable to explain the phenomenon, the quite frequent presence of albumen in the urine, without tube-casts, or any other sign of renal disease, and yet I can hardly believe the albumen to be merely due to cystitis, for if that were so, it should be constantly present.

In one instance I have followed for four years the history of a man who drinks to excess. At the beginning of, and for a time before, his attacks of delirium tremens, while he is consuming alcohol freely, he often has bloody urine, which will contain tube-casts of all varieties at different times, fatty, hyaline, and granular. When he ceases his consumption of alcohol, as he has quite frequently done for two or three months at a time, the urine becomes normal, as far as chemical tests and microscopic examinations will reveal its condition. In the light of this case, how can we believe that the abuse of alcohol does not produce renal degenerations? Is not this man sure to die of Bright's disease, if he continues his indulgence in alcohol?

Another case was a man over fifty years of age, who was seized with rheumatism; he progressed badly, and was much more sick than the amount of rheumatism would seem to warrant, and at last, after about three weeks, died; having obstruction of the bowel, and inflammation of the kidneys, as shown by the presence of albumen and tube-casts in the urine; also hydrothorax and extreme stupor, which seemed uræmic. This man had had an attack of influenza about three or four weeks previous to his fatal illness. Can there be any connection between the severe influenza and the rheumatism, and renal inflammation and obstruction of the bowel, of which this patient died?

The last case I will mention was a boy, who died very suddenly of congestion of the lungs, probably the first stage of pneumonia. A trace of albumen and granular casts were found in his urine, which was obtained a short time before death. This boy was about sixteen years of age, and did not seem much sick on the afternoon of one day, being up and dressed, the next morning dying, in a state of maniacal delirium, with his lungs extremely congested. There was, unfortunately, no post-mortem examination made. This case would seem one in which the pulmonary affection was primary, and yet it might be that he had a latent contracting kidney.

There has been much said of later years about kidney disease without the presence of tube-casts in the urine, and of the presence of casts without albumen. I may say that I have frequently found tube-casts in the urine when the most careful chemical examination failed to detect any albumen, and *vice versa*, have failed to find any casts at all, when the event proved the existence of renal disease.

The subject of treatment I have not even mentioned in my paper, although much might be said about it, because I have already trespassed too long upon your time.

In conclusion, I will briefly recapitulate the points which it has been my endeavor in this paper to prove.

First, that in no ordinary, uncomplicated case of Bright's disease, should a prognosis of speedy death, or even of incurable disease, be given, for I have related cases in which the disease was chronic, lasting more than two years, and which ended in complete recovery, and others, in which the person affected has lived nearly nine years.

Second, that dyspnœa, usually taking the form of renal asthma, is much more common than is usually supposed, and when properly appreciated, is a valuable diagnostic sign of the disease; also that severe coryza is a complication or accompaniment, and has a diagnostic value.

Third, that Bright's disease, as a cause of death, is on the increase.

Fourth, that it is a very common cause of the deaths of old people, probably being the direct cause in many deaths reported as of old age.

Fifth, that the passage of gravel, even when microscopic in size, but particularly if large enough to cause nephritic colic, is a prolific cause of the disease.

Sixth, that the occurrence of tube-casts in the urine, without, or in advance of, the presence of albumen, is very common, and *vice versa*, persons may die of Bright's disease, and the most careful examination fail to show any tube-casts, although there may be albumen constantly present in the urine.

Seventh, that the abuse of alcohol is certainly a cause of kidney disease, as proved by the case I have related, in which it has, again and again, caused hemorrhage from the kidney, with the temporary presence of albumen and tube-casts in the urine, disappearing again with the cessation of its consumption.

Dr. R. P. Harris said that he had observed, in cases of albuminuria, vomiting as a frequent symptom, and regarded it of diagnostic importance.

Dr. H. C. Wood asked, with regard to those cases of Bright's disease, in which neither albumen nor tube-casts were found in the urine on examination. In a case of this character, coming under his observation, he had based the diagnosis on the low specific gravity, and the diminished secretion of the urine.

Dr. J. Solis Cohen said he had long been aware of some special association between laryngeal and renal diseases, and had attributed this to disturbance of circulation at the base of the brain, affecting both the renal nerves and the pneumogastric.

Dr. James Tyson said the subject of albuminuria was so extensive and presented so many phases that one is at a loss where to commence in its discussion; but he believed Dr. Meigs quite right in saying that the more one studies it the more unwilling one is to interpret it dogmatically. He thought, however, that there are some cases in which a quite positive position can be taken. To illustrate: with contracted kidney or interstitial nephritis, he thought the presence of hypertrophy of the heart a symptom which justified an unfavorable prognosis, while in cases of contracted kidney in which this stage has not been reached, it was most difficult to approximate the time of termination. He had seen persons apparently at the point of death recover so far as to be able to resume their occupations, while others apparently in the vigor of health succumbed in a few days with uræmic symptoms. Generally, death soon succeeds upon the occurrence of uræmic convulsions, and Dr. T. could not recall a case in which they were not followed by an early death in this form of kidney disease.

Again in cases of chronic parenchymatous nephritis where there are large numbers of highly fatty cells, oil casts, and free oil drops, while the patient exhibits a pallid whiteness which suggests the almost total absence of red-blood corpuscles, recovery is scarcely possible. On the other hand, he had seen many cases in which oil-casts were in the urine, recover completely.

Dr. Tyson could not, however, accept the quotation by Dr. Meigs, from Grainger Stewart, as expressing the exact truth. It is not strictly true that every form of cast may be found in every form of Bright's disease. Blood casts are not found in uncomplicated chronic Bright's disease; and, although it is common to find hyaline casts containing a few oil drops in chronically contracted kidney, highly fatty casts are never present. He did not desire to be considered as saying that casts are of conclusive value in diagnosis, but in many cases they are of great assistance. It is more particularly in the subacute and chronic forms of parenchymatous nephritis and amyloid disease that we have the same varieties of casts present, and find them consequently of little value in diagnosis.

Much is said now-a-days of albuminuria in health. But Dr. T. thought that however complete may be the absence of symptoms accompanying an albuminuria, he could not consider the kidney from which filtered a continuous albuminous urine to be in a normal state.

With regard to the question of Dr. Wood, he thought that, even throwing out those cases in which albumen and casts are overlooked by the observer in consequence of carelessness, haste, or inexperience, it was possible that there might be Bright's disease without either albumen or casts. But he had never met an instance. In such a case he would consider the symptom mentioned by Dr. Wood—low specific gravity along with a greatly diminished urine—one of the most conclusive possible.

Dr. Bruen called attention to the prognosis of catarrhal diseases of the kidney—classed as Bright's diseases. When these forms of renal disease were associated with severe catarrhal lesions in the lungs, the renal disease accelerated the fatal issue.

But sometimes catarrhal lesions were a single severe expression of general catarrhal inflammation—sometimes of local catarrhs. The etiology of these forms of renal disease offers most favorable vantage to the physician for basing his prognosis. The prognosis is good in these cases—when the heart is hypertrophied and an adequate circulation is maintained—bad in proportion to advance of cardiac mischief. Prognosis then should be made from six months to six months. In *Guy's Hospital Reports* for 1881, are to be found a number of cases of Bright's diseases without albuminuria, by Mahomed. Dr. Bruen called Dr. Wood's attention to these cases, and expressed a belief that a close study of the sphygmograph tracings would be of great assistance. Further the character of the cardiac sounds indicate the strength of the heart. This arterial fibrosis, with cardiac hypertrophy, accompanies most markedly the forms of Bright's disease in which the interstitial changes predominate over the tubular. The urine in these cases though it may not exhibit albumen will often exhibit casts, mostly hyaline, slightly granular.

Dr. Bruen called attention to the value of the shallow cell in the examination of the urine, when the casts are but few. This method is highly recommended by Dr. Johnson, and Dr. Bruen desired to elicit the experience of others as to the necessity of examining urine in a small cell, in all doubtful cases when casts might be supposed to be at a minimum.

Dr. Geo. C. Harlan spoke of the great importance of an examination of the eye-ground in Bright's disease, and of its value in a diagnostic point of view.

Dr. Arthur V. Meigs, in closing the discussion, said that his paper was a purely clinical one, and was intended merely to record observations made in study-

ing the sixty-two cases of albuminuria mentioned. It would self-evidently be impossible, in so short a compass, to attempt to give even a *résumé*, which would be exhaustive of so vast a subject as the one under discussion. With regard to the observation of Dr. Wood, that Bright's disease might exist without either albumen or tube-casts being present in the urine, he thought it a fact which could not be denied. As to the possibility of making a diagnosis under the circumstances, the observation of Dr. Wood that a small amount of urine of low specific gravity passed continuously for a length of time, and that of Dr. Harlan that the ophthalmoscope might sometimes lead us to a positive conclusion, seemed at present our best, if not only, means of making such a diagnosis. Vomiting is a common accompaniment or symptom of renal disease. He agreed entirely with Dr. Tyson, that in a certain class of cases of Bright's disease a very exact diagnosis was possible, and a prognosis too, but in other instances, particularly in patients advanced in life, and with the disease somewhat latent, even an approximation of the future duration of life was impossible.

Dr. Addinell Hewson presented the

Report of a Case of Cervical Lymphadenoma Treated by the Application of Earth.

He said: my reason specially for wishing to present the patient to-night is not only to describe the symptoms of this interesting disease but to show that it has been more than arrested in its course—that it is actually undergoing positive dissipation, and that, too, by what has alone been used with it from the very first of my treatment.

The following is the history:

P. M., aged 53 years, was born in Ireland, of healthy parents, who brought him to this country when he was over 17 years of age. His father died not long since, aged 72 years. His mother is still alive, but has always been, since her earliest recollections, a sufferer with arthritic rheumatism. There is no tendency on either side of the family to phthisis. He had always, prior to the first manifestations of his disease, enjoyed most excellent health, and by a long practical experience in machine shops, foundries and in the working of steam engines, he was well qualified to fill the post of an engineer, which he obtained at Girard College in 1877, and has faithfully filled ever since. There, as I have been informed, he has displayed zeal and industry not only in his own duties, properly speaking, but by making himself always useful whenever occasion might occur. Thus on the occasion of the preparation of the meals of the college, he was not only watching the conditions of the engines and boilers of its grand culinary arrangements, but was always willing and ready to assist any one with whom he might there be brought in contact. So, on a summons, he was prompt to go from one of the very hot rooms of the kitchen to one of an equally opposite temperature, in the refrigerator, large rooms made as cold as ice could make them, in which meats and other articles of food were perfectly preserved.

It was after one of these exposures that he was seized with the first symptoms of cervical lymphadenoma. Then two weeks before Christmas 1880, one year and nine months ago, he was long enough in one of these refrigerators to get all his clothing thoroughly wet and his body so chilled that he became prostrated. This exposure was followed by a general reaction and a pain in the right supra-clavicular fossa. These chills and fevers were constantly recurring for several days, and those of the second period of twenty-four hours were specially characterized by a kindred pain in the left supra-clavicular fossa. The pains of both sides subsequently extended up to the occiput and from there down the spinal column, becoming more intense at its fundamental end. With the latter there was numbness or partial want of sensation not only of his lower extremities, but all over, except, as he says, in his hands. His throat was from the first sore and his speech about a year ago became so indistinct as not to be readily understood. Three months later his hearing, on the left side, was absent, and five months later he became partially deaf in the right, not being able to hear then the ticking of a watch beyond twelve inches.

The temperature of the neck was at first highest on the left side, and continued so until last Christmas when it became, by far, the highest on the right side. He had then been treated from the first for sore throat, by gargles and medicines, anodynes, alteratives, and the like. These he continued up to the time of his coming to me. During the period to which I have referred he had both of his ears inflated by the Eustachian catheter and gum bag, by an attendant at the clinic of one of our public charities. This inflation was followed by much pain, especially in the left ear, which continued up to the time of my first seeing him, when hearing in that ear was absent. I then tested the hearing of the right ear by an English lever watch, and so showed it to be no more than eight inches.

When I first saw him, June 21, 1882, he presented a most singular appearance with his occiput and chin both drawn downwards and forwards, and his shoulders upwards, inwards, and forwards. His face was the very picture of distress. The room in which he was had, in the little time he had to await my coming there, became so impregnated by the smell from him as to make it stink like an opossum's kennel. This was still perceptible there more than an hour after his leaving the room. The patient has always admitted that this fetor came constantly from him and was often the subject of comment or of complaint by those about him. A close inspection at the first soon satisfied me that it was from the skin of the sides of the neck and from there only that the whole stench came. This was demonstrated as a fact beyond all cavil or doubt, by its complete dissipation in a few days by the dressings I used.

This poor fellow was sitting astride of a chair in the room, when I went in, gasping for breath, with a loud, irregular, stridulous respiration, whilst he supported his head by both his hands. By considerable effort he made me understand that his distresses all came from the tumors on his neck which he had all ready to uncover and show to me. Whilst he was doing so, however, I had walked partially around him, and got my first full view of his neck from behind. It there looked as if he had two necks attached to the base of his head. The growths on the right side, projecting beyond the line of the outer border of the trapezius there for a width equal to that of the whole neck, and the excrescences on the left side, produced this appearance. He then managed to tell me that his sufferings were incessant, that he had not been able, for a long time, to maintain his head when erect without the aid of a hand or some other means of support, except for a few moments; and that he could not, from a very early date of his troubles, lie down and sleep in any position over a period of twenty minutes, as he was always then startled by a feeling of impending suffocation.

The urine possessed a sp. gr. for that of the evening of 1017, and for that of the morning of 1021. Microscopic examination revealed the presence of phosphates. The quantity of urine voided in twenty hours was, according to his statement, about normal.

His pulse was decidedly frequent (102) and feeble, evidently somewhat so disturbed then by nervous

agitation. His respirations were likewise disturbed, and the impulse of his heart was feeble and diffused.

The mucous membranes of his lips, mouth, and tongue were very red and swollen. This condition being most marked around the gums and being associated with positive looseness of the teeth, at once suggested the probability of pytalism being present. The patient stated that he could not masticate any solid food or swallow any hot liquid.

His tonsils and uvula, as also his half arches and walls of the pharynx, were likewise much swollen and reddened, and efforts to inflate the middle ears by forced inspirations and expirations on his part whilst the mouth and nostrils were held tightly closed, showed that the Eustachian tubes were both completely obstructed, and although he was then free from all signs of catarrh in either antra and forehead, it was evident that the obstructions in the Eustachian tubes were, like those of the external, due to the immense size of the tumor on the outside of the neck.

The contour of these tumefactions was limited essentially to the lateral regions of the neck. Starting in the supra-clavicular fossa on either side they were greatest at first, posteriorly, along the planes of the trapezii muscles. Those muscles were, on both sides, much stretched and pressed backwards, and were very markedly defined by this backward prominence of the tumor.

The tumor, then, on both sides extended high up behind the ear, covering both mastoid prominences, but did not extend further back there than the outer attachments of the trapezii to the occiput. In front of the ears they went up to the zygomatic processes of the malar bones projecting outwards in front of each ear to more than an inch from the jaw.

The front lines of these projections dipped down to the base of the jaw on either side for an inch in front of the anterior auricular processes of the external meatuses covering up to some extent the ears, as seen from in front, and giving a strange appearance to the face by hiding the ears, and this was intensified by the hair of the beard there.

The swellings extended forwards on both sides of the face along and close to the base of the lower jaw, and as far forwards as the front of the submaxillary glands. These glands themselves were greatly increased in size; that of the right side being of the size of a hen's egg, whilst that of the left was half that size. They both projected for more than half their thickness beyond the line of the lower jaw, and furnished by the anterior extremities the limits of the growth there. Indeed a line drawn perpendicularly downwards from those extremities showed that the tumors of both sides did not come any further forward, lower down than those points, and a critical examination of the region of the larynx and of the sternal extremities of the sterno-cleido-mastoid muscles, showed that the central portions of those muscles passed through the tumors, or more accurately, that the tumors were developed there on the *inside* as well as the outside of those muscles.

To preserve as definite an idea as possible of these growths, I took and kept one set of tracings, by means of a long strip of sheet-lead one inch wide and one-eighth of an inch thick, which I placed, when well warmed by friction on their surface, along lines extending from the outer margins of the trapezii forwards and two fingers' breadth below and parallel with the base of the jaw, and as far forwards there as the anterior border of the sterno-cleido-mastoid muscles. These secured the *three fixed points* by which I could subsequently make tracings for comparison.

The actual measurements which I made before my dressing were for a line drawn across the neck just three inches below the occipital protuberance, seven and one half inches for a like line in the back, horizontal with that of the clavicles in front eleven inches, and for a line straight across the tip of one shoulder to that of the other, fifteen and one-half inches.

The measurements obtained after one week's treatment were, for the first of these three lines, six inches, a reduction of one and a half inches; for the second line nine inches, a reduction of two inches; and for the third line a trifle over sixteen inches, which being a difference in singular contrast with those of the other two lines, caused momentary surprise, but was soon found to be explicable by the increased freedom of motion of the shoulder of the right side, which allowed it to be carried well back.

At the end of the *second* week similar measurements, indicated by the interrupted blue lines dotted with red spots, the third set across the backs of the neck and shoulders were respectively five, nine, and sixteen inches, showing a change only for the first of the series.

Then, as I have said, the original infiltration into the subcutaneous cellular tissue had become so completely dissipated that the real *lymphomatous* character of the growth was to be readily recognized, and was commented upon by Prof. Jas. Tyson, who saw the patient on the morning of the fifteenth day, when I was applying the dressings. A sulcus had then formed on each side, separating very well, and defining clearly the cervical from the supra-clavicular portions. These sulcii became very great during this, the third week, especially on the right side, and they grew essentially at the expense of the truly cervical portions of the tumor.

At the end of the third week of my treatment the posterior borders of the tumors on each side had so ceased to be on the plane of the trapezii that I could not make any more tracings to be used for correct contrasts. The widest or most projecting portions of the tumors were then in the centres of the sides of the neck, that of the left side being nothing more than what would represent the natural contour of the neck there.

The patient had now not only recovered freedom of motion, lateral rotation, and flexion of his neck, but could hold himself perfectly erect. This has made an actual difference in his stature of one inch and a half over what it was at his first visit to me. His breathing became natural as early as the fifth day of my taking charge of him. He was then (June 26) able to lie down and sleep without any anodynes for twelve hours at a time, a thing he had not been able to do since the first of his attack, although he had always been treated by the free use of vegetable narcotics, bromides, and other saline sedatives. I had forbid his using anything of the kind on the night of my first seeing him. With this came improvement of his pulse, his appetite, and his general nutrition. These improvements have continued steadily going on up to the present time, the end of the eleventh week to-night since I first saw him. His complexion which was then markedly leukæmic, is now ruddy and as healthy looking as could be desired. He has regained his hearing perfectly on both sides. He has no signs of pharyngeal irritation or constriction. His voice is full and clear. His pains and hyperæsthesia of the integuments covering the growth disappeared in the first week, and have never returned.

Treatment.—This patient had never been without treatment since the onset of his attack. He saw his family physician on the next morning, who treated him first for a bad cold; then, and up to a short time before I saw him, by various constitutional remedies, such as iodides and bromides and other alteratives, and locally

by the application of tincture of iodine, blisters, and poultices. With them all the patient had, however, not obtained the least sign of relief. On the contrary, he said he had continued to grow worse up to the time of my prescribing for him. I then advised him to stop the administration of these remedies, and fearing that so sudden and complete a stoppage of the anodynes, to which he had long since become habituated, might occasion distress to his nervous system, prescribed the tincture of avena sativa, ten drops of which he was to take in hot water at bedtime every night. He took but two doses of that remedy, for on the third night he was so freed of all pain and distress that he went to bed without taking any, and slept the night through. With this single exception I have not given him anything since his first visit to my office, but have relied solely on a daily application of yellow clayey earth. This I have put on in the form of a smooth paste, thick enough to make it hold fast to the integuments of all parts where there was any swelling. This paste I made with water by means of an ivory spatula. By the latter I also made the application all over the tumefaction to the thickness of an eighth of an inch, laying on top of this a firm film of cotton batting, so as to have the clay fixed and held tightly in its place after it became dry, and until the shrinkage of the tumefaction would become such that free spaces were readily to be detected between the inner surface of the dry clay and the outer surface of the tumor. The necessity for renewing the clayey dressing was apparent every day. Indeed, after the patient had recovered his power of free motion of his neck, he did not maintain the applications in their places a whole day at a time. He never, however, washed the parts. What was left of the clay hanging to the integuments showed in itself the fact of shrinkage following the drying of each application. I dressed him in this way with the clay only once every day for eight weeks.

At the end of two months the shrinkage was such that the tumors on both sides were no longer so easily disturbed as regards their coverings by the movements of the neck. The tumors themselves were then so reduced in thickness that they were, on the left side, only small subcutaneous fragments or nodules of what was originally there, and on the right they occupied small spaces in the supra-clavicular fossa, the outer surface of the sterno-cleido-mastoid and the like surface of the submaxillary gland, all being so free by passive motion that their coverings with the earth were nothing like as easily disturbed as they were originally by the movements of the neck. For these reasons I entrusted the daily applications to the man's wife and himself. He says, however, that the applications do not hold as long and as well as my most recent ones.

In spite of all obstacles to the purely earth treatment, I am well satisfied with the progress of destruction which has taken place in this case, and my special object of bringing the patient here this evening is to show his present condition, in order that it may be compared with that which the subsequent treatment will effect.

NEWS ITEMS.

THE FEES OF PRESIDENT GARFIELD'S PHYSICIANS.—The following claims have been filed by the physicians in attendance with the board designated by Congress to audit the claims arising from the illness and death of the late President James A. Garfield. Dr. D. W. Bliss, $25,000; Dr. D. Hayes Agnew, $14,700; Dr. Robert Reyburn, $10,800; Dr. D. S. Lamb, for examination of the body at Elberon, New Jersey, $1000. No claim has been filed by Dr. Frank H. Hamilton.

YELLOW FEVER IN PENSACOLA.—The telegraphic despatches show the fever continuing, with perhaps a slight tendency to decrease. Up to and including October 9, there have been 1300 cases, and 114 deaths.

Dates.	Cases.	Deaths.
October 10th,	50	3
" 11th,	56	7

Aug. 28th to Sept. 18th,	217	29
Week ending Sept. 25th,	300	25
" " Oct. 2d,	358	33
" " " 9th,	425	27
" " " 16th,	380	29
Total,	1680	143

This disease has spread to within sight of the picket line of the Navy yard, cases having occurred on the other side of the Big Bayou. The line is strictly guarded, and the people on the reserve continue hopeful that they may escape visitation. Occasionally a case of bilious remittent causes considerable excitement until its true character is determined. A general conflagration last week destroyed the supplies of provisions, but a relief steamer from Mobile is daily expected.

SEMI-CENTENNIAL CELEBRATION OF THE MEDICAL FACULTY OF MCGILL UNIVERSITY.—The Medical Faculty of McGill University celebrated their Fiftieth Anniversary by a conversazione, on Wednesday, Oct. 6th, when an historical address was delivered by Dr. R. P. Howard, the Dean of the Faculty of Medicine, and by a banquet on the evening of Oct. 7th.

Dr. Howard entered upon a review of the Faculty since its inception fifty years ago. After referring to the laying of the corner-stone of the present Montreal General Hospital, on the 6th of June, 1821, he said the first Canadian medical school was established by five of the hospital staff, Drs. Stephens, Robertson, Holmes, Caldwell, and Loedel. During the first session twenty-five students attended, not one of whom now survive. The first lecture-room was in a small wooden building in the Place d'Armes, where the Bank of Montreal now stands. The next event in the history of the early days of the Faculty, was the bequest by the Hon. James McGill. In the year 1811 he bequeathed a valuable property and £10,000 currency for the purpose of endowing the College which was to bear his name, and form part of the University, which it was believed was the intention of His Majesty George III. to establish in Montreal. In 182c the royal charter was obtained for McGill College, but litigation as to the will prevented possession of the estate till 1829. On the 29th of June, of that year, the Montreal Medical Institution was constituted the Medical Faculty of the College, and the first session of that Faculty was held in 1829–30, at which 35 students attended, and since then its lectures have been continued annually, except during the three years comprised in 1836-39, so that the present is its 50th session.

After speaking at some length of the formation of the University, he proceeded to sketch briefly the lives of the four men who were the founders of medical teaching in Canada—Dr. Andrew Fernando Holmes, who

died in the year 1860, and during the last eight years of his life, was Dean of the Medical Faculty; Dr. John Stephenson, who, from the records of the Montreal General Hospital, had probably the honor of originating the medical institution, and who died in 1842; Dr. Wm. Robertson, who died in 1842, and Dr. Wm. Caldwell, who died in 1833.

He concluded with an elaborate eulogy of the late Dr. George W. Campbell, former Dean of the College. He suggested the establishment of a faculty fund in memory of the late Dean, to be known as the "Campbell Memorial Fund." Yet such a fund established by citizens, would be a graceful tribute to the memory of a good man and an able physician, and at the same time a gratifying evidence that the Faculty's career and work have merited their approval.

The guests were then invited to the upper hall, and the conversazione was opened. It was a most brilliant reunion, all the professions being well represented. The band of the 65th Rifles played an excellent programme of music. Refreshments were served from several tables.

There were about 200 guests present at the banquet, including some of the most distinguished members of the medical profession, not only graduates of McGill, but also representatives from other famous medical institutions, besides several members of other professions and leading business men of the city of Montreal. The chair was occupied by Dr. R. P. Howard, Dean of the Medical Faculty. On his right sat his Honor, Lieutenant-Governor Robitaille, who by a happy coincidence was not only the representative of the Queen in the Province, but was also a physician and graduate of McGill College; he responded at length, to the toast of the "Lieutenant-Governor of Quebec." Principal Dawson responded to the toast of "The Principal of the University."

Dr. James R. Chadwick, representing Harvard University, responded to the toast "Sister Colleges," as did also Dr. Burkham, President of the University of Vermont, Dr. Workman, of the old Toronto School of Medicine, D. D. Osennens, of Victoria College, Dr. Covernton, of Trinity College, Toronto, and Dr. F. W. Campbell, of the Medical Faculty of Bishop's College.

In the course of the dinner, Dr. Howard announced that he had just received a letter which might justly be termed the first fruits of the appeal that he had made on the previous evening, as to the necessity of an endowment for the Medical Faculty. The writer, whose name he could not divulge, said, "that the remarks in the admirable address of last evening, on the necessity for increased means to enable you to extend and render still more efficient the work of your Faculty, impressed me so strongly that I shall be glad to assist in procuring this, and now make the proposition that if by the first of August next, you succeed in securing the $50,000 referred to as the Campbell Memorial Fund, I shall have the pleasure of handing you an additional $50,000, for the purpose of the Medical Faculty of McGill University." This announcement was received with enthusiastic applause.

The Annual Report of the Surgeon-General of the Marine-hospital Service has just been received. From it we learn that during the fiscal year ending June 30, 1882, 36,184 patients received relief from this Service, of whom 13,048 were treated in the hospitals and 23,136 at the different dispensaries; 333,475 days' relief in hospital were furnished; 312 trusses, 23 elastic stockings, 8 knee-caps, 7 pairs crutches, and other appliances have been issued to outgoing patients. Transportation to their homes has been furnished to 7 incurable patients.

The number of seamen treated shows an increase of 3,571 over last year.

In addition to the relief furnished, as shown above, 273 seamen in the Revenue-Marine Service and 33 seamen of the Light-House and Merchant Service have been examined, and 2,090 pilots have been examined for color-blindness.

Of late years there has been a great change in the manner of furnishing supplies to the various hospitals and relief-stations of this Service. Instead of purchasing them at the ports in limited quantity, and of such quality as might be procurable, the supplies are now bought by contract, delivered at Washington, and are inspected and repacked for distribution. This insures uniformity in the character of supplies, and, as far as medicines are concerned, their chemical purity.

There were thirty-six applications for appointment to the Medical Corps, and fifteen candidates appeared for examination, eight of whom passed, and seven were appointed into the Service, taking rank in order of merit.

The recommendation for the establishment of a marine hospital at Cincinnati has been concurred in by Congress, and an appropriation made.

The construction of the marine hospital at Memphis has not yet been commenced, owing to the difficulty in procuring the title to the site selected.

The examination of pilots for color-blindness has been continued during the past year. The following case is given as illustrating in a marked degree the efficacy of the Holmgren worsteds as a test for color-blindness:

A pilot on one of the revenue steamers was examined by a medical officer of this Service and pronounced color-blind. He appealed from this decision, and requested that a board be appointed to examine him. The board reported, as the result of the examination, that with the green skein he matched brown and orange; with the purple he put blue; and he repeatedly matched the colors as stated. The board was "of the opinion that Mr. —— is color-blind. He is otherwise physically qualified to perform the duties of a pilot." This report was forwarded to the Secretary with the following indorsement: ". . . . From the report of the board it will be seen that Mr. —— is green-blind and red-blind."

The friends of the party being still dissatisfied with the report, and claiming that in the Merchant Service he would be entitled to a re-examination by signal lights, the Secretary ordered the examination to be so made. The following is the report of the board:

Mr. C. was first shown into a dark room, where two green lights were burning — one, the standard; the other, green, but not up to the standard. After some hesitation, both were pronounced red. Then the change was made to both red, which he, after the some hesitation, pronounced both green. Then red and green were shown. These he got correct, but immediately changed the red to green; and then, when asked to state definitely, changed back. On the fourth trial, the red and green were shown, and the answer was correct. On the fifth trial a red was shown alone, and the answer was correct. Then this was removed and another red was put in its place—the change being made in full view of the applicant; this he pronounced green.

In view of the above facts, as developed by these tests, the local inspectors were satisfied that the applicant is unable to "sufficiently distinguish the colored lights on steam-vessels," and therefore refused to grant the license asked for.

It is gratifying to learn that the above and one other are the only cases in which the verdict of the skeins has been called in question during the past year. The pilots are now satisfied of the perfect fairness and effi-

ciency of the test. In the other case the applicant came all the way from the Pacific coast to lay his case before the Department, and he was re-examined in this office. The skein test showed green-blindness. An unanswerable proof of the infirmity of the applicant was given when a scarlet book was held against a white wall until the complementary color appeared. The spectators were requested to write on a slip of paper the name of the complementary color as it appeared to to them; which they did. The applicant was then asked to name the color, which he was entirely unable to do, saying it all looked "the color of the wall." others had, however, written on their respective slips "pale" green and "light" green. This experiment is strongly corroborative of the scientific propriety of the term color-*blindness* as applied to absence of color-sense.

Election of Officers of the Pathological Society of Philadelphia.—At a stated meeting, held Thursday, October 12, 1882, the following officers were elected for the ensuing year: *President*—James Tyson, M.D. *Vice-Presidents*—J. Solis Cohen, M.D., F. P. Henry, M.D., E. O. Shakespeare, M.D., J. B. Roberts, M.D. *Secretary*—P. G. Skillern, M.D. *Recorder*—C. B. Nancrede, M.D. *Treasurer*—M. S. French, M.D. *Curator*—Carl Seiler, M.D.

American Academy of Medicine.—The Seventh Annual Meeting of the American Academy of Medicine, will be held in the hall of the College of Physicians, Thirteenth and Locust streets, Philadelphia, on Thursday, October 26, at 3 o'clock P.M. Dr. Traill Green, of Easton, Pa., the President, will deliver an address at 8 P.M., Thursday, October 26, to which the profession is invited.

Foster's Physiology has been translated into Italian by Prof. Michele Lessona.

Personal.—Prof. Gussenbauer, of Prague, has refused the call to Würzburg to fill the vacancy caused by Bergmann's removal to Berlin.

Profs. Socin of Basle, and Mars of Freiburg, have been proposed by the Medical Faculty of Würzburg as the successor of Prof. Bergmann.

Dr. Marion Sims.—Dr. Marion Sims sails for Europe shortly, and will spend the winter in Rome for the recuperation of his health.

Prof. Rossbach, the Professor of Pharmacology in Würzburg, who has been called to Jena as the successor to Nothnagel, has accepted the position and will commence his course during the present winter term.

Memorial of Becquerel.—A statue has been erected at Châtillon-sur-Loing, in memory of Becquerel, the eminent physicist. MM. Dumas and Frenuz made eulogistic addresses at the inaugural ceremonies held on September 24.

Gift to University College Hospital (London).—Mrs. Nathaniel Montefiore has given £2,600 to University College Hospital, for the endowment of two beds in memory of her late brother, Sir Francis Henry Goldsmith, Bart., and her late son, Mr. Leonard Montefiore.

Died, on September 19th, Dr. Edward Cox, of Battle Creek, Michigan, in the 67th year of his age. Dr. Cox was one of the pioneer physicians of the West, and was in 1878 President of the Michigan State Medical Association. He was an able writer and took quite a prominent part in politics.

Ergot in some Affections of the Bones.—At the recent Congress for the Advancement of the Sciences, held at Rochelle, M. de Musgrave-Clay, of Pau, read an interesting paper on this subject, in which he mentioned a case of white swelling of the neck, occurring in a child six years of age, in which the administration of powdered ergot greatly reduced the pain and swelling, and arrested the suppurative inflammation of the bone. He states that no danger of poisoning need be feared in its prolonged use.—*Bull. Gén. de Thérap.*, September 30, 1882.

Births in Paris.—From September 8th to September 17th there were 1154 births in Paris: of these, of the male sex, 419 were legitimate, 156 illegitimate; of females, 437 were legitimate, 152 illegitimate.—*Le Progrès Méd.*, September 23, 1882.

Health Reports.—The Sanitary Engineer proposes to publish the most important data collected by the National Board of Health, and heretofore published in the *Bulletin* of the National Board of Health, the latter having been discontinued on account of the refusal of Congress to grant the necessary appropriation for defraying the expenses of its issue.

A Town Clerk's Health Report.—Dr. J. T. Reeve, Secretary of the State Board of Health of Wisconsin, in the annual report of the Board for 1881, just published, refers to the difficulties he encountered in obtaining statistics from certain townships. To facilitate the collection of the necessary *data*, he distributed a blank form of the annual report, to be filled up and returned. Generally, very satisfactory responses were made; but in one case "the Clerk returned no answer to any communication for two or three years; finally, the blanks were enclosed in a sealed envelope, addressed to the most important office in the township, and indorsed with a request to the Postmaster to forward them to the official in question. This plan succeeded, and the following choice epistle from the Clerk was received in answer: 'I should like it if the Ligislatures would appropriate about $1000,000 to be dewided between the Town Clerks for making the 1000 and once repor's which are sent to us dayly. They institute offices and appoint Cummissioners so as to feed a lot of politicians which they need to run eelections. The Town Clerks has to do the runing, picking up Statistics gratis free and for nothing and the Cummissioners draws a good salary will (with ?) a few days of actual Labor.' This document, which is given *verbatim et literatim*, was written on a scrap of paper, apparently torn from the bottom of an old letter, and forwarded as the report from a town of about 1,800 people, and is the only report ever yet received by this Board concerning the health and sanitary conditions of the community in question."

Night Medical Service for Brooklyn.—Brooklyn is about to follow New York and Washington in the establishment of a night medical service.

Immigrant Inspection Service; National Board of Health; Operations in the Western District during the Month of September, 1882.—Supervising Inspector Rauch reports that during the past month there have arrived and been inspected in this District, comprising the States of Indiana, Illinois, and Missouri, a total of 14,404 immigrants, of which number 2,918, or

about one-fifth were found imperfectly or not at all protected against smallpox, liable to contract the disease and to propagate the contagion. Of these, 234 had never before been vaccinated, among which were many adults.

There were found in transitu five cases of smallpox which were removed to hospitals in St. Louis and Chicago respectively, the necessary precautions taken with those who had been exposed, and the cars and belongings thoroughly cleansed and disinfected. Of these cases, the inspectors have made full and detailed reports, that of Inspector Starkweather being as follows:

September 6.—Found a case of modified smallpox in the person of a single woman, thirty-nine years of age, coming from a small town near Manchester, England, and bound for Neenah, Wisconsin. She had been vaccinated only once—and then in infancy. She presented a card certifying that she was vaccinated, signed by the surgeon of the steamship *Scythia* of the Cunard Line. On the obverse was the following, printed in English and four other languages: "*Keep this card to avoid detention at quarantine and on railroads in the United States.*"

The patient occupied passenger car No. 424 of Pennsylvania Railroad. The rash appeared on Monday A. M., September 4th, or before the time of leaving the ship. The ship's surgeon did not look at her arms she said, nor so far as I could ascertain did he do any vaccinating of his people, and made only a very superficial and worthless inspection. The eruption must have appeared sixty hours before the time I first saw her. It was located upon the forehead, cheeks, neck, and upper extremities somewhat abundantly; none apparent upon lower limbs. The patient said it was prickly heat, and that she would soon be over it if allowed to go on to Neenah,

Oscar C. DeWolf, M.D., Health Commissioner of this city, saw the patient with me in consultation on the car at my request, partly to satisfy the patient and partly to protect the Inspection Service and railroad corporation against possible malicious action for damages in the future. She made no opposition to being taken in the ambulance to the smallpox hospital. The car was thoroughly fumigated by the City Health Department, and the necessary instructions were given to the railway company concerning its present use.

I vaccinated sixty-five adults, who had been more or less exposed on the train, the railroad officials cheerfully and courteously rendering every needful assistance. Two of the people whom I vaccinated at their own request, belonged to the crew of the train.

This case was detected before leaving Valparaiso, Ind., but partly owing to want of facilities at any point nearer than Chicago, it was brought on to that city for treatment—every precaution being meanwhile taken to prevent any exposure of others during the remainder of the journey.

The cases, four in number, removed to the hospital in St. Louis, were detected while still in Illinois. These were found among a party of Bohemians bound for Missouri, have all since convalesced and been discharged. So far as has been ascertained, no other cases have been caused by these.

The importation into Ford county, Ill., reported in my last (see The Medical News, Sept. 16, 1882, p. 336), gave rise to three other cases, of which one terminated fatally. (This was the importation by a horse-dealer returning from France on a stock-boat, the *Friga*, which boat, it is alleged, escaped inspection at New York quarantine. The horse-dealer, Hefner, contracted his disease from a case of modified smallpox which occurred during the voyage. As he did not travel as an immigrant in this country, he was not seen by any of our inspectors.) The outbreak was confined to one family, and danger of any further spread is not now anticipated.

Concerning the character of the protective work done by steamship surgeons, there is still the same disparity noted as has been commented upon before. Passengers arriving by vessels of the same line present the most marked contrasts. On one, the surgeon will have made a careful inspection and have vaccinated or revaccinated all unprotected or doubtful cases; on the very next arrival by the same line, evidences of gross carelessness will be found in children of all ages holding the surgeon's cards, but without any personal evidence of ever having been vaccinated; and, in the case of adults, not revaccinated since infancy, but similarly equipped with cards to secure them, in several languages, "against detention on railroads in the United States."

Copies of my previous reports, forwarded to the officers of the various lines, have in many cases, it is believed, been productive of improvement in this respect; but the steamship medical service is not yet by any means what it should be in its treatment of immigrant passengers with regard to the preservation of health. In the absence of any adequate national legislation prohibiting the introduction of foreign pestilence, and the want of proper State and local legislation, I know of no better method of securing the result, under present conditions, than by giving publicity to the character of the work done by each surgeon, as shown in the condition of the immigrants passing through his hands and arriving in the interior.

Unprotected immigrants, susceptible to smallpox and capable of propagating the contagion, have been received in this district during the past month from the following vessels:

Steamships Abyssinia, Wyoming, and Arizona, Guion line.

Australia, Westphalia, and Leipzig, Hamburg-American line.

Bermuda, line not reported.

Brittannic and Germanic, White Star line.

British Crown, Lord Clive, Ohio, and Pennsylvania, American line.

Canada, Trans-Atlantic Company.

Circassia, Anchor line.

City of Chester and City of Montreal, Inman line.

Dupuy de Lome, Compagnie Commerciale des Transports a Vapeur Francais.

Edam and Pollux, Royal Netherlands line.

England and The Queen, National line.

State of Georgia and State of Nebraska, State Steamship Company.

Main and Strasburg, North German Lloyd's.

Ontario, Dominion line.

Parthia, Malta, and Pavonia, Cunard line.

Plantyn, White Cross line.

The most notable line for disregard of vaccinal protection of its passengers is the American, of Philadelphia. In one instance, twelve passengers out of fifty by the steamer Pennsylvania, of this line, were found totally unprotected, never having been vaccinated at all. Yet every one had been furnished a steamship protection card. This proportion will hardly hold good throughout, but the number of unprotected by this line is far in excess of any other.

In gratifying contrast to the foregoing exhibit is that made by the surgeons of the following-named vessels, many of them belonging to the lines above enumerated, but on which the vaccinal service appears to be thorough, the inspections careful, and the vaccinations and re-vaccinations effective:

Allan Line: Sardinia.

Anchor Line: Ethiopia.

Cunard Line: Samaria, Servia, Cephalonia.

Dominion Line: Dominion.
Great Western Line: Gloucester.
Guion Line: Iowa.
Hamburg-American Line: Bohemia, Gen. Werder, Wieland, Frisia, Vandalia, Gellert.
Inman Line: City of Chester, City of Berlin, City of Paris.
Monarch Line: Grecian Monarch.
National Line: Helvetia, Spain, Egypt.
Netherlands-American Line: Schiedam.
North German Lloyd's: Salier, Nurnberg, Elbe.
Red Star Line: Vaderland, Pennland, Belgenland, Switzerland, Waesland.
Royal Netherlands Line: Surrey, Jason.
State Steamship Co: State of Florida, State of Missouri, State of Indiana.
Stettiner-Lloyd's: C. H. Schultz.
Thingvalla Company: Hekla, Island.
Trans-Atlantic Steamship Company: France, Amerique, St. Laurent.
White Star Line: Baltic.

One inspector notes the difference in passengers arriving by vessels of the same line at Boston and at New York, and attributes the superiority of those arriving at the former port to the character of its inspection service. I have also had occasion to note that we have had, in Illinois, but one case (a mild varioloid) which could be attributed to Boston, in something over a year.

Evidence of the growing interest in this protective measure, is found in the increasing numbers of immigrants vaccinated, or revaccinated just before sailing. This is especially true of the English and Scotch, and in a great measure offsets the occasional opposition to the inspection, met with from individuals of the same nationalities, and which seems to be due to the anti-vaccinationists of Great Britain.

Vaccination performed at this time, *i. e.*, prior to sailing, has the advantage of enabling the steamship surgeon to judge of its effectiveness during the voyage; and it would be a decided improvement on the present general plan, of waiting until the last days of the voyage, if the surgeon would perform the operation as soon after leaving port as practicable. This would give him an opportunity of noting the value of the virus and result of his work, besides facilitating the labor of inspection upon and after arrival. I think that a circular letter from the Board, making this request of the managers of the various steamship lines, would meet with a favorable reception.

The disparity in the results of vaccination performed on shipboard is due, possibly, as much to the method of performing the operation as to the character of the virus employed, though there is, doubtless, much of this used which has become inert, either from being kept too long or from exposure to the salt, moist atmosphere. Both of these evils would be more likely to be remedied if the surgeon was able to follow up the results of his work.

As all doubtful cases in this District, that is, those in which the evidence of proper vaccinal protection is not clear and unmistakable, are carefully vaccinated with virus seldom more than seventy-two hours from the heifer, it is probable that those passing through our hands are more thoroughly protected than many of our citizens.

Recent action in England, detailed in the following, will tend to still further lighten the responsibility of this Service:

Dr. Bloxall, R. N., one of the medical inspectors of the local Government Board, accompanied by Capt. Wilson, representing the Board of Trade, has opened at Liverpool an inquiry with regard to certain sanitary questions connected with emigration, and as to the circumstances in which emigrants passing through the port of Liverpool are placed before sailing. He is likewise instructed to inquire as to the provision made for the isolation and treatment of sick persons arriving from infected places on the Continent or in the United Kingdoms; and, further, as to the sanitary arrangements and supervision of the lodging-houses into which emigrants are received, and the means taken with respect to infectious diseases occurring therein.

In a few instances the cars have been found wet and dirty, especially those transferred from connecting lines; but, as a rule, their sanitary condition is quite satisfactory.

Cholera infantum among children, and diarrhœa among adults were quite frequently met with in the early part of the month. One child died *en route* of the former disease. Measles and chicken-pox have appeared often enough to keep the inspectors on the alert and to demand the exercise of discretion and prudence in dealing with their subjects.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending October 7, 1882, indicate that erysipelas has increased, and that cholera infantum, cholera morbus, bronchitis, and influenza have decreased in area of prevalence.

Compared with the average of reports for the months of October in the preceding five years, all diseases except puerperal fever, were less widely prevalent during the week ending October 7, 1882, than usual.

Including reports by regular observers, and by others, diphtheria was reported present during the week ending October 7, and since, at 20 places, scarlet fever at 11 places, and measles at one place. One case of smallpox was reported at Grand Rapids, October 9.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 9 TO OCTOBER 16, 1882.

GRAY, W. W., *First Lieutenant and Assistant Surgeon.*—To be relieved from duty in Department of the Columbia, and to report in person to Commanding General, Department of the South, for assignment.—*S. O. 237, A. G. O., October* 11, 1882.

BARNETT, RICHARDS, *Captain and Assistant Surgeon.*—Relieved from duty in Department of the Platte, and to report in person to Commanding General, Department of the East, for assignment.—*S. O. 237, A. G. O., October* 11, 1882.

CRAMPTON, LOUIS W., *Captain and Assistant Surgeon.*—To be relieved from duty in Department of Dakota, and to report in person to Commanding General, Department of the East, for assignment.—*S. O. 237, A. G. O., October* 11, 1882.

BRECHEMIN, LOUIS, *Assistant Surgeon.*—Relieved from duty in Department of Dakota, and to report in person to Commanding General, Department of the East, for assignment.—*S. O. 237, A. G. O., October* 11, 1882.

WAKEMAN, W. J., *Assistant Surgeon.*—Upon being relieved at Fort Douglas, Utah Territory, to proceed to Fort Fred Steele, Wyoming Territory, and report for duty.—*S. O. 106, Department of the Platte, Oct.* 6, 1882.

KANE, JOHN J., *Assistant Surgeon.*—Granted leave of absence for one month, with permission to apply for extension of three months.—*S. O. 202, Department of the Missouri, October* 9, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

LARDACEOUS DISEASE OF THE LIVER.

A Clinical Lecture delivered at the Philadelphia Hospital, September 13, 1882.

BY JAMES TYSON, M.D.,

PROFESSOR OF MORBID ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA AND ONE OF THE PHYSICIANS TO THE PHILADELPHIA HOSPITAL, ETC.

GENTLEMEN: The patient whom you see is thirty-two years of age, an American by birth, and by occupation a puddler. His family history is good, and he himself enjoyed excellent health until September, 1879, when he suffered an injury to his right hip, while lifting a piece of cast-iron. The exact nature of the original injury is not known to us, nor does it immediately concern us. Sooner or later, however, there became established suppurative disease of the bone with fistulous openings, from which discharge is continuous. Of possible importance in connection with the diagnosis is the fact that he was operated upon for *fistula in ano* in February, 1880. The information is not definite, but the operation may have been necessitated by the burrowing of pus in the ischio-rectal tissues. He denies ever having had syphilis.

About six months ago, that is to say, in the month of March, his abdomen began to enlarge, and the enlargement has slowly continued until, at this time, it is evident to superficial examination, and closer inspection shows the prominence to be rather more upon the right side than the left, that is, in the right hypochondrium.

Proceeding to determine the area of enlargement by percussion, we note in the mammillary line, percussing downwards, that dulness begins at the sixth rib. Now this is not higher than the upper border of the liver at this point in health. Indeed, you will find, in some of your text-books, the upper border of the liver in the mammillary line noted as being in the fifth interspace. Proceeding downwards with our percussion, we find that, instead of ceasing at the free edge of the ribs, dulness extends at least four inches below that border. In the median axillary line we note the upper border of dulness at the seventh intercostal space, also in the normal position. But again the lower boundary is far below the edge of the ribs in this line, almost at the crest of the ilium. Anteriorly, also, in the median line, the lower border of the liver, instead of extending only about one-half the distance from the end of the ensiform cartilage to the umbilicus, is found at least two-thirds the way down between these points.

We can only conclude from such an examination that the liver is enlarged. But what is the cause of the enlargement? What is the disease from which our patient is suffering? In the first place, what are the diseases in which the liver suffers enlargement? They include acute congestion, hepatitis, abscess, cancer, hydatid disease, fatty liver, and lardaceous disease. In the first two there is, at most, moderate enlargement, never anything like we find here. There is also tenderness over the region of the liver. Upon very decided pressure there is, in our patient, some flinching, but the tenderness is not marked. There are none of the other symptoms of these conditions, no fever, no headache, no nausea, constipation, or coated tongue; no pain or weight in the right side, or pain in the right shoulder; no jaundice. I think we may, therefore, safely exclude hepatitis and acute congestion. In *abscess* there are the same symptoms more intensified, with possible fluctuation. We need not pause, therefore, to further discuss abscess.

In *cancer*, on the other hand, we have enlargement of the liver, quite as marked as in this instance, and at times even more so. But it would be impossible for the enlargement to reach this degree without cachectic symptoms which are here absent. Indeed, one would scarcely suppose from inspection of the man's face that he is very ill. Again the surface of the enlarged liver of cancer is often uneven or bossilated from the presence of nodules, which can sometimes be felt through the abdominal walls. But the surface of the liver in our patient is quite smooth. Finally cancer of the liver is rarely primary. There is almost always a tumor elsewhere. Here there is not. Cancer may as well, therefore, be excluded from the possible diseases.

The *fatty liver* is also an enlarged liver, and it is a smooth liver as well. But it rarely becomes as large as the organ in the patient before us. Further, it is attended by other exhaustive disease, especially consumption, and is caused by hard drinking and syphilis, none of which are here present.

Hydatid disease of the liver is also attended by enlargement. But here again we have irregular enlargement of the organ, instead of the smooth enlargement here present. In other respects the symptoms are not dissimilar, in the absence of pain and tenderness. We must, therefore, look about us for something which will further aid us to distinguish these two conditions. Lardaceous disease is rarely confined to the liver alone. Most commonly there is simultaneous enlargement of the spleen, and upon examining this organ we find that instead of the usual area of two inches square, which does not extend anterior to the median axillary line nor below the edge of the ribs, we find it occupying a large area of at least four inches square. The kidneys are also sometimes involved in this change, and we recognize it by the presence of albuminuria, but in this case there is none. Enough has been said to make it plain that only one of the diseases discussed can be here present, and that is lardaceous or amyloid disease.

But what is lardaceous disease? It is a disease in which first the cells, and finally all the tissues of the organ, become infiltrated with a peculiar albuminoid substance, the effect of which is to cause them to swell, and assume a glassy lustre, and by the aggregation of these enlarged cells there is produced a corresponding enlargement of the entire organ. This is the infiltration which Virchow first observed, and, in consequence of the peculiar reaction which he noted, called it amyloid substance, though erroneously. The reaction he observed was a blue color, by the addition of iodine and sulphuric acid; whence he concluded that the infiltrating material was amyloid or starchy. This conclusion was soon found to be erroneous, as the substance turned out to be albuminous in composition, while the reaction is by no means a constant one. On the other hand a very constant reaction is that by iodine alone, which strikes a mahogany red color with the amyloid substance, instead of the brown color which is usually produced by treating albuminous tissues with iodine.

A very pretty reaction is also that of anilin violet (a 1 per cent. solution), which strikes a red or pink color with the amyloid material, while the unal-

tered tissues are stained blue, whence a beautiful contrast results.

Most important is a study of the causes which bring about this form of disease, because it will presently be seen that our almost sole power of treatment lies in prevention, rather than cure of the already formed disease. The cause of this form of disease is pretty well determined, and it is found to be either syphilis, or the long-continued presence of some exhaustive drain upon the system, such as occurs in protracted disease of bone with suppuration, phthisis accompanied by copious expectoration, or even long-continued albuminuria. In the patient before us, we are aware of the existence of disease about the head of the thigh-bone for at least two and a half years before the liver began to enlarge, and with the knowledge we have of the causation of the disease, I think we may assert with some positiveness that the hip disease is the cause of the lardaceous infiltration of the liver and spleen.

As to treatment and prognosis, it is evident from what has been said in discussing the etiology that we cannot hope for marked results while the cause is in operation. His hip is full of sinuses, indicating caries of the bone, and it becomes a very nice question, to solve which we must call in the aid of the surgeon, whether operative interference is here justifiable or likely to be attended with beneficial results. The question is further complicated by the fact that there is *existing* lardaceous disease of the liver and spleen, and the question whether, even supposing the bone disease could be cured, we could then get rid of the amyloid condition of the liver. I must say I do not recall a case thus far advanced which has been cured. Nevertheless, it is evident that it is more likely to get well with the causative disease removed than when it is present, and if there is a reasonable prospect of success, an operation directed to the removal of the cause should be performed.

Admitting, as all now do, that surgical diseases are a frequent cause of lardaceous disease, it is nevertheless true that this fact is often overlooked by surgeons, and operations are delayed when a recollection of possible results would suggest earlier operation, and avert the unfortunate complication.

When syphilis is the cause of lardaceous disease, the treatment for syphilis is the treatment for the visceral affection, and it is, of course, the treatment for the secondary and tertiary forms. The persistent use of small doses (by which are meant doses of from $\frac{1}{60}$th to $\frac{1}{32}$th of a grain) of iodide of mercury with iodide of potassium is indicated. It is by no means certain that iodide of potassium has the same effect in reducing parenchymatous overgrowth as it has upon interstitial hyperplasias in the liver, but there is, at any rate, no contraindication to its use, and in the present case I have ordered it to be continued in moderate doses of five grains, before each meal, freely diluted. And this is important, for it has been determined that the effect of iodide of potassium upon the liver, at least, is very much more rapid when administered fasting and freely diluted, than when given after meals and undiluted.[1]

When phthisis is the cause of the lardaceous disease, the treatment of the pulmonary affection is that of the former. Here cod-liver oil and iodide of iron, with abundant nutritious food, and all possible favorable hygienic influences, are indicated. And it may be said of lardaceous disease from any cause, that a supporting plan of treatment is essential, whatever may be the special indications due to special causes.

[1] See a valuable paper on this subject by Dr. J. M. Guiteras in the Philadelphia Medical Times, vol. x., 1880.

TWIN PREGNANCY, WITH PERITONEAL DROPSY.

PARACENTESIS, RESULTING IN THE EXPULSION OF THE FŒTUSES PRIOR TO THE SIXTH MONTH OF PREGNANCY; RETENTION AND ABSORPTION OF THE PLACENTÆ, WITH RECOVERY.

BY GEORGE ROWLAND, M.D.,
OF COVINGTON, INDIANA.

(Read before the Fountain County, Indiana, Medical Society.)

My object in this article is to invite attention to the subject of pregnancy complicated with ascites, and the practical importance of an early correct diagnosis.

Effusions within the abdomen may occupy three separate locations, or even more than three; thus during pregnancy, effusions may accumulate within the amnion, and form what is known as dropsy of the amnion; also, effusions may form between the membranes of the ovum and internal surface of the uterus, giving rise to what is known as hydrometra, or dropsy of the womb; and lastly, effusions of fluid may accumulate within the cavity of the peritoneum, giving rise to a true ascites.

Either one of such effusions, accumulating during pregnancy, is comparatively of rare occurrence. It has been said of these dropsies, that they may occur separately, or two of them may co-exist in the same female.

This affection usually makes its appearance in the first half of pregnancy, usually about the fifth or sixth month, but rarely later. When, however, the dropsical effusion begins at an early stage of pregnancy, it sometimes progresses so rapidly that the abdomen may at the fifth month become as large as at the usual term of gestation.

The progress of peritoneal dropsy increases rapidly; the face is puffed; the abdominal walls, thickened by infiltration, present a glistening appearance. The umbilicus forms a smooth, rounded tumor, sometimes translucent, at the base of which is the umbilical ring. This peculiar character of the umbilicus is very important to the physician in making his diagnosis, as the sequel will show. The labia share also in the general infiltration, and are largely swollen. The skin of the lower extremities is greatly distended, is exceedingly painful, and occasionally bursts in a few instances.

But probably of all the symptoms, dyspnœa is the one of which the patient complains the most. It is in this distressing condition that the physician is implored to give assistance. All the organs of the thorax are crowded upon, their functions are obstructed, dyspnœa becomes extreme, respiration is short and painful. The patient at all times is obliged to remain propped in an arm-chair, both day and night, and yet in this position the conversion of venous into arterial blood is so imperfect that every instant she seems to be threatened with suffocation. This distress is aggravated by constant insomnia, headache, extreme thirst, and disgust for food. Percussion and palpation of the abdomen very readily detect a large amount of fluid within its

cavity, though in the following instance it was not equal in all of its parts. The books tell us it is generally absent, or nearly so, in the hypogastrium, much more clear in the hypochondrium, and very well marked in the left hypochondriac region, near the cartilages of the left false ribs.

The large accumulation and enormous distention of the parietes of the abdomen prevent the uterus from being felt and its position determined, and whether or not pregnancy exists is very difficult to determine with any precision. The motions of the fœtus, though obscure, may be felt by the mother, but the presence of a fœtus in utero is one of great difficulty to determine. The large and distended abdomen prevents auscultation from being of any service in determining whether or not pregnancy exists. In the delicate manipulations of ballottement and agitations of the fœtus in utero, or of the uterus itself, which is one of the least equivocal signs of pregnancy, when abdominal dropsy exists, very little can be learned, owing to the great amount of liquid accumulated within the abdominal walls.

Abdominal dropsy, complicated with pregnancy, is a grave affection, and more particularly when in the early stages of gestation. When it occurs in the latter months of pregnancy, there is reason to hope it will be arrested by the delivery of the fœtus before producing any serious disorder, compromising the life of the mother. But when the effusion begins in the first half of pregnancy, there is great cause for alarm, and should the effusions progress rapidly, paracentesis will be demanded long before the ninth month.

The following is a case that was under my care for several weeks, of a woman who during pregnancy had a large accumulation of liquid within the abdomen, requiring paracentesis to relieve urgent dyspnœa, which resulted in the expulsion of two fœtuses, at about five and a half months of gestation:

Mrs. C. aged 37, mother of three children, related the following history: "Was in good health prior to April, 1881. During that month my monthlies ceased; I then suspected I was pregnant. Had no morning sickness, as was usual in my former pregnancies. Did not notice anything particular as to my appetite. My breasts did not increase in size, and nothing was particularly wrong, except my monthlies had ceased. I have three living children, and had two miscarriages, both of which occurred since birth of my youngest child. I felt as well as usual until the first of June, 1881. Then I first noticed my abdomen to gradually increase in size. My urine decreased in quantity, and was very black. Some days I would only pass one-half pint of urine in twenty-four hours. I drank much water, and I had a constant intense thirst. My abdomen continued to increase in size, and my breathing was so difficult that I would almost suffocate. My urine continued to decrease in quantity, and my thirst was never assuaged."

This was the condition in which I found the patient on September 10. After a careful examination of the case, one of the questions was, did pregnancy exist? It will be remembered that the menses ceased in April, and that the abdomen rapidly increased in size after the first of June. On the part of the patient, no signs of pregnancy existed, save that of the cessation of the menses. There had been no motion of the fœtus felt by the mother. There was great enlargement of the abdomen, but by percussion, fluctuation was produced, showing that a large amount of fluid was evidently in its cavity.

There was no umbilical depression, as we have in natural pregnancy, but instead there was an umbilical tumor. The phenomena presented by the mammæ did not confirm pregnancy. On making a vaginal examination, both in the erect and recumbent positions nothing definite could be ascertained. Neither could anything be learned by the usual manipulations and auscultations, that would indicate positively that pregnancy existed. No sounds of the fœtal heart could be heard, and those who claim to be able to detect a twin pregnancy by auscultation might have met with a failure in this instance.

After making a summary of all the symptoms in the case, it was pronounced abdominal dropsy without pregnancy, but with a possibility of there being pregnancy. Paracentesis was recommended, but the patient declined, choosing rather to resort to the usual medicinal remedies, hoping thus to remove the fluid through the emunctories; but vain hope! After a trail of the hydragogues and diuretics, as far as it was prudent to push such remedies, they proved to be of little value. They were resorted to by myself with reluctance, and were relinquished as soon as found to be unsuccessful.

Finally the accumulation of fluids increased so rapidly and to such an extent that the life of the mother was threatened by suffocation, and it was evident that the only means of saving her life was the immediate evacuation of the fluid.

But the question was, where should the puncture be made? If pregnancy existed, the woman was between five and six months of gestation. At this stage of simple uterine pregnancy the fundus of the uterus is an inch above the umbilicus. The development of the uterus thus makes it impracticable to insert the trocar at the usual place of insertion in ordinary ascites, which is from one to two inches below the umbilicus.

The most prominent fluctuation was in the left hypochondrium, and was greatest near the edge of the false ribs, and instances are recorded where the trocar was introduced between the uppermost part of the external border of the rectus muscle and the edge of the false ribs, in the left hypochondrium.

Furthermore, it is very important, before the operation of paracentesis is performed, where there is a possibility of pregnancy existing, to be clear in the diagnosis as to whether we have dropsy of the uterus or dropsy of the peritoneum. The uterus may be distended by fluid to the size which it usually has at the end of gestation, and such a distended uterus may present all the external appearances of an abdominal dropsy.

A dropsy of the uterus may be distinguished from a dropsy of the peritoneum. In peritoneal dropsy the urine is small in quantity and turbid; great thirst; percussion produces fluctuation, which

is more perceptible at the upper than at the lower part of the abdomen.

In dropsy of the uterus the abdomen may be as large as at the ninth month, but fluctuation is obscure, no thirst, and urine in normal quantity.

Thus it was clear that the case under consideration was that of peritoneal dropsy, and such it was pronounced.

On the 22d of September, I introduced a trocar and canula two inches below the umbilicus through the abdominal walls, and drew thirteen pints of clear liquid away. The effect was immediate relief of all the urgent symptoms, and the patient was left an anodyne for the night, promising to call next day. Within twenty hours the woman was seized with labor pains, and in one hour after I reached the house she gave birth to a fœtus, which immediately expired. On making an internal examination, a second fœtus was discovered, with breast presentation. With but little difficulty it was converted to a foot presentation and removed.

There was little loss of blood—none of any consequence. The uterus was rather sluggish in contracting, and the placenta gave no evidence of being removed. Waiting sufficient time, the left hand was introduced into the uterus, with the expectation of removing them, but here another difficulty presented itself, which was either an hour-glass contraction of the uterus or an enlarged placentæ.

Before the true state of affairs could be ascertained, and while the hand was within the uterus, the patient was seized with syncope, lasting nearly two hours. Restoratives were administered, producing rest and sleep, and further counsel requested. Dr. G. S. Jones was called in consultation, and after careful consideration of the case for forty-eight hours, it was decided to make no interference, but trust to restoratives, nourishing diet, with quinia in conjunction with weak carbolic acid solution injection into the uterus. This treatment, with slight variations, was continued for two weeks; the patient rapidly recovered, and on the eleventh day after the operation of paracentesis, she walked across the room and was able to sit up part of the day. Up to the date of writing, Oct. 6, 1881, there has been no removal of the placenta, there is no abdominal dropsy, the kidneys secreting normal quantity of urine, no dyspnœa, no thirst, but instead there is every indication of a rapid and good recovery.

P. S.—At this date, Jan. 30, 1882, the patient having recovered over three months, and no expulsion of placenta, and there being evidence of their absorption.

NOTES ON A CASE OF IDIOPATHIC RETRO-PHARYNGEAL ABSCESS, WITH SOME OBSERVATIONS ON DIAGNOSIS AND TREATMENT.

By ALEXANDER W. MacCOY, M.D.,
MEMBER OF THE PHILADELPHIA LARYNGOLOGICAL SOCIETY.

On August 8, 1882, Robert H. Clark, æt. 43, native, widower with three children, presented himself for treatment at the Jefferson Medical College Hospital.

The history he gave was as follows: he never had syphilis; early in July, after having been under great anxiety and physical exhaustion from nursing a sick wife, he first felt a slight pain on deglutition. Shortly after, a slight stiffness of the neck, followed by increasing rigidity, became apparent, accompanied by flexion of the head forwards, which soon became so marked as to force his chin upon his chest. Extension of the neck was impossible. As the neck became rigid he began to suffer from an excruciating, lancinating pain—which darted upwards into back and sides of the head, extending as far as the vault. He described this pain as terrible in the extreme. Slowness and difficulty in swallowing increased, soon followed by inability to take solid food. With great care, small quantities of liquids could be slowly swallowed, although frequently the fluid would come out of his nostrils. A short time after his attack began, he put himself under the care of a physician; he continued under his care for some time, when, no relief being afforded, his physician referred him to the Throat Department of Jefferson Medical College Hospital.

Upon admission, patient's face was thin and worn; head flexed on chest, rotation could be moderately effected, and there was a slight fulness of the neck on the right side, beneath the angle of the jaw, with enlarged lymphatics; voice thick, and difficult to understand; respiration somewhat impaired; mouth could be opened sufficiently to admit tongue depressor or finger.

Examination: After the tongue had been gently depressed, a much swollen soft palate and uvula were seen, red and dusky in color. The uvula was pushed well forward into the oral cavity, and very tense. Below the soft palate on the right side, the posterior wall of the pharynx could be seen bulging forward to the base of the tongue, filling up the entire space of the pharynx from before backwards and extending well over beyond the median line to the left. Examination by the finger showed the swelling extending about an inch above the soft palate, but increasing in tension from above downwards until, on a level with the superior margin of the larynx, it was greatest. The swelling appeared to extend about a half inch below the aperture of the larynx. The epiglottis was pushed up against the base of the tongue. On examination with the finger the bulging was found to be elastic, and to show fluctuation. Laryngoscopic examination could not be effected.

Treatment consisted of a small vertical incision about a half inch in depth, and a half inch in length, made with a guarded bistoury, which gave vent to a free flow of pus—pale yellow, thin, and free from odor. Four ounces in all were evacuated. Relief to all of his distressing symptoms was immediate. The contents of the abscess were evacuated (as in the previous case reported by me[1]) two or three times a week by passing a probe into the incision, and pumping out the contents with the finger, pressing from below upwards. This manipulation was employed in six or eight sittings. The

[1] Med. and Surg. Reporter, March 25, 1882.

discharge grew rapidly less, and the pus cavity, which was large, gradually filled up with plastic material, and finally became obliterated.

Remarks.—During the year's service at the Throat Department at Jefferson Medical College Hospital, there have been three cases of retro-pharyngeal abscess under treatment. Two of these were idiopathic, occurring at the respective ages of 24 and 43 years; the remaining case (a colored boy æt. 14, under the care of Dr. Jurist, who kindly allows me to refer to it) appeared to arise in a constitution profoundly impressed from birth with scrofula, which was probably dependent upon congenital syphilis. This latter case died from secondary basilar meningitis, with a suspicion of an abscess at the base of the brain. The autopsy, which was only allowed upon the vertebræ, showed no disease of their structure. The pus cavity between the posterior wall of the pharynx, and bodies of the vertebræ extended above to the basilar process of the occipital bone, and below to a level with the cricoid cartilage. The fact most impressed upon the mind of the writer from the observation of these three cases, was that there was a mistaken diagnosis in every case by the attending physicians. One case was treated with liniments, etc., nearly four weeks for rheumatism of the neck. Another case, (the boy) had many opinions expressed by his several attending physicians, none of which were at all correct. The third case, (reported above) appeared to have been treated for tonsillitis, as well as could be determined from the medicine prescribed—tincture of iron and chlorate of potassium.

These errors in diagnosis, made by good practitioners, appear more surprising to a specialist in diseases of the throat than they do to the general practitioner, because the specialist has peculiar appliances and methods for examination of these affections, which are overlooked by the mass of practitioners; noticeably, a good light and palpation with the index finger well into the pharynx. By palpation in this manner, an abscess can hardly be mistaken after pus has formed. In the judgment of the writer, all cases of retro-pharyngeal abscess, where no disease of the vertebræ is present, give indications of early formation of pus. In all three cases mentioned in this paper, pus had undoubtedly been present for weeks, and had caused, from its accumulation and mechanical interference, a serious train of suffering accompanied by impending starvation, which could have been so readily and promptly relieved. Abscess in this quarter occurs so seldom that the physician is generally off his guard. This fact, coupled with those already mentioned—insufficient illumination, faulty and incomplete examination of the throat—makes the mistaken diagnosis almost a certain sequence.

The treatment consists in prompt surgical interference as soon as pus has formed. The evacuation of the pus can be accomplished best by one of two procedures: evacuation by a small vertical incision as high up as the free border of the soft palate, and not low down at the point of greatest tension, as would be generally selected; or by aspiration, which is a safe and satisfactory method. In infants and children, where exhaustion is always marked, and danger of suffocation from entrance of pus into the larynx imminent, aspiration can be employed with so little risk, and with so much facility, that, in the judgment of the writer, it should supersede all other methods. After the tension of the abscess has been relieved (either by the small vertical incision, or with the aspirating needle) and thereby all risk avoided from the flow of pus, the incision can be somewhat extended, or take the place of the needle. An opening lower down can then be safely made if desirable. The writer does not ever advise a free incision, lest particles of food and drink, or atmospheric air, get into the sac. For the same reason, he prefers the incision high up and very small in extent.

The accumulation of pus can be pumped out from time to time, satisfactorily, with the finger, until the cavity has become filled with reparative material. It is doubtful if any surgical interference from the outside of the oral cavity, made with a view to reach the abscess, is ever justifiable.

Philadelphia, 1417 Walnut St.

MEDICAL PROGRESS.

Acute Primary Retro-laryngeal Abscess.—Dr. Goix concludes an elaborate study on this subject as follows:

1. Acute primary retro-laryngeal abscess consists in an inflammation of the connective tissue in the retro-laryngeal space.

2. Its appearance is characterized by the simultaneous occurrence of fever, laryngeal pain, feebleness and hoarseness of voice, cough, dysphagia, and symptoms of laryngeal stenosis.

3. Normally, when moved from side to side, the posterior edges of the thyroid cartilage may be felt to glide over the vertebral column; this *thyro-vertebral friction* disappears in retro-pharyngeal abscess, but persists when the abscess occupies the retro-laryngeal space.

4. The gravity of this disease cannot be explained by the mere interference with respiration from œdema of the glottis; the inflammatory irritation of the various laryngeal nerves should also be taken into consideration.

5. The best treatment seems to consist in the administration of large doses of tartar emetic and the application of several blisters. If tracheotomy is required by the urgency of the symptoms, the pus should be evacuated, even after this operation.—*Arch. Gén. de Méd.*, October, 1882.

Paget's Disease of the Nipple.—It is of the utmost importance to come to a definite conclusion with regard to the nature of this disease, whether it is primarily of an eczematous nature ultimately terminating in cancer, or whether it is of a malignant nature from the outset, as the treatment, of course, must vary according to the view we adopt. Prof. McCall Anderson has seen a number of cases of this disease and believes that in persons predisposed to cancer, any local irritation may determine an outbreak of the disease at the part irritated; thus we have frequently seen an undoubted syphilitic disease of the tongue followed by cancer of that part, as the result of the long-continued irritation; and just in the same way it is possible for a simple eczema of the breast to prove the exciting cause of, and to be followed by, cancer of the mammary

gland. But if we exclude these exceptional cases, we can arrive at no other opinion than that "Paget's disease of the nipple," is from the first of a malignant nature, and bears a somewhat similar relation to cancer of the breast that the so-called tylosis (or psoriasis) linguæ does to epithelioma of the tongue. Such being the case, it is of the utmost importance to distinguish true eczema of the breast from "Paget's disease of the nipple," towards which the following may be of assistance:

1. "Paget's disease of the nipple" occurs especially in women who have passed the grand climacteric. Eczema of the nipple and areola occurs especially in women earlier in life, and particularly during lactation, or in persons laboring under scabies.

2. Affected surface, in typical cases of Paget's disease, of brilliant red color, raw and granular-looking after the removal of crusts. Surface not so red and raw looking in eczema, and not granular, but often punctated.

3. When grasped between the thumb and forefinger, superficial induration often felt, in Paget's disease, as if a penny were laid on a soft elastic surface and grasped through a piece of cloth (Thin). Eczema is soft, and no induration.

4. Edge of eruption abrupt and sharply cut, and often elevated, in Paget's disease. Edge not so abrupt, and not elevated, in eczema.

5. Paget's disease is very obstinate, and only yields to extirpation or other treatment applicable to epithelioma generally. The other disease, although sometimes obstinate, yields to treatment applicable to eczema.—*Glasgow Medical Journal*, October, 1882.

Resection of the Hip under Antiseptic Precautions.—Boeckel (*Gaz. méd. de Strasbourg*, 1, 1882) advises resection in suppurative hip disease in cases where the patient is failing, and in the non-suppurative cases where crepitation is marked. If the external surroundings of the patient are good, in suppurative cases he advises incision, emptying of the pus, and drainage. The indication is the same in acute osteo-myelitis and ostitis juxta epiphysaria. He favors subtrochanteric incision, and removal, as far as possible, of the fungous synovial membrane and clearing the acetabulum. The external incision is not sewed. Extension is to be applied for several weeks. At the end of four to six weeks the patient is allowed to get up, extension being applied at night, crutches and a raised shoe on the well foot being used in the daytime. In from three to four months the limb can be used. The author reports a small number of cases, but with good result.

Grosch (*Centralb. f. Chir.*, 14, 1882) has collected one hundred and sixty-six cases of this operation, done under strict antiseptic precautions. In presenting the cases he has grouped them under heads corresponding to the condition of the joint at the time of the operation. The first stage he classifies as that where the pathological change is slight, and where the suppuration, slight in amount, has not worked to the outside. In the second stage fall those cases with extensive suppuration and established fistulæ. The third class comprises those patients who have become much reduced by prolonged and extensive disease. Out of one hundred and twenty cases watched to the end, forty-four died, a mortality of 36.7 per cent., a percentage which corresponds with that of Guy's Hospital, Volkman's klinic, or the Copenhaven clinique, and is lower than Culbertson's tables taken from cases not all treated antiseptically, and is much lower than Leisrink's mortality before the introduction of the antiseptic method, 64 per cent. Furthermore, dividing the cases into two groups, those occurring between 1870 and 1875, during the apprenticeship of the antiseptic technique, the percentage of mortality was 9 per cent higher than since that time. The mortality in the first stage of the disease among children was 0 per cent., in the second stage 24.1 per cent., and in the third 67.5 per cent. Antiseptic dressings do not seem to have effected any change as to the usefulness of the cured limb as compared to that before the method was introduced. This is a matter which is not yet definitely settled, but a number of cases were established where an almost normal usefulness of the limb remained unimpaired many years after the operation.

Where, during the operation, perforation of the acetabulum occurred, the percentage of mortality increased twenty per cent.

The writer further found that the duration needed for recovery was not influenced by the antiseptic method of dressing, but it gave a greater immunity against wound complications.—*Boston Medical and Surgical Journal*, October 12, 1882.

Resection of a Carcinomatous Pylorus.—Dr. Eugene Hahn reports the case of a woman aged 63, in whom he excised the pylorus for a cancerous tumor. Billroth's method of operation was followed in all its details, with the exception that he employed the Lembert suture in preference to the method advocated by Czerny, while he adopted the plan of Wölfler, in passing the first sutures through the posterior wall and fastening them on the mucous surface, thus reducing the difficulty in applying the final sutures. Four days after the operation the patient was still doing well, no elevation of temperature being present, and the vomiting which was troublesome on the day after the operation having been relieved; but on the seventh day violent vomiting again appeared, and the patient died under the symptoms of peritonitis from perforation. At the autopsy several of the sutures were found to have given away.—*Berliner klin. Woch.*, Sept. 11, 1882.

Cases of Removal of a Portion of Intestine.—Dr. Wm. Fuller reports in the New York *Medical Record*, Oct. 14th, three cases of partial intestinal resection for strangulated hernia; recovery took place in all.

Cholera and Filth.—The exact nature of the relation between cholera and filth is a subject admitting of speculation and discussion, and the question will not be satisfactorily solved until the precise cause of cholera has been demonstrated; but of the reality of the relation as a matter of fact there can be no reasonable dispute. Strong evidence exists in Calcutta which goes to support the doctrine that, whatever the nature or cause of cholera may be, filth has much to do, if not with its origin, certainly with its propagation—filth in air, water, and food; filth due to neglected conservancy; filth consisting mainly of the decomposing excreta of men and animals. The history of cholera in this town points to a marked abatement of the disease coinciding with important sanitary improvements, more especially with the introduction of a supply of pure water and its distribution in such a manner as to prevent contamination in transit. The most important fact shown by the report of the Health Officer of Calcutta, is that the sections which exhibit the lowest general death rates are those in which the sanitary conditions are most favorable, in which the streets are widest and best kept, the houses largest and sparsest, the drainage most complete and efficient, pure water universally used, and the inhabitants most observant of the rules of hygiene, domestic and individual; while on the contrary the sections with highest death rate are the most crowded and filthy, with narrow, muddy

streets often heaped with refuse and rubbish, foul pits and ditches, ill-kept stables and byres, wells and tanks filled with diluted sewage, with numerous *bustis* or villages ill-ventilated, over-crowded, and filthy, in which the poorer classes, ignorant and careless as regards cleanliness, mass themselves together in poverty and squalor.—*Indian Medical Gazette*, Sept. 1, 1882.

Prolapse of the Large Intestine; Resection; Death.—Prof. Auffret, of Brest, reports the case of a young woman, aged 25 years, with marked rachitic deformities of the limbs, who had for three years suffered from obstinate constipation, to overcome which she was in the habit of using all sorts of cathartics and injections. On the 26th of October, after prolonged straining she had a prolapse of the large intestine, about 35 cm. in length, which it was impossible to replace by taxis. On the following day, the prolapsed portion of the bowel was excised, and the divided end of the large intestine united by catgut sutures to the mucous membrane of the large intestine just within the anus. The patient died of collapse during the night after the operation.—*Le Progrès Médicale*, Aug. 26, 1882.

Comparative Action of the Bromides.—MM. Chéron and Fouques, having experimented at some length with the three well-known bromides (of potassium, sodium, and ammonium), have reached the following conclusions: These salts act, in virtue of their bromine, as moderators of the reflex centres. The bromide of potassium joins to its sedative action on the nervous centres a depressing action on the muscular system; it is thus a *neuro-muscular* agent. The bromide of sodium has an action like that of bromide of potassium on the nervous centres, but does not affect the muscular system; it is thus simply a *moderator of reflex action*. The bromide of ammonium has, in virtue of its bromine, an action on the nervous system similar to that of the other two, while it is also, in virtue of its ammonia, an excitant and diffusible; it is thus at once a *moderator of reflex action* and a *peripheral excitant*. Consequently, when it is desired to influence the reflex powers and the muscular system, preference should be given to the bromide of potassium; if, however, we wish to act only on the reflex centres, the bromide of sodium is indicated; finally, if, leaving the muscular system out of consideration, it is desired to act on the nervous centres, to restrain the circulation and to effect a diminution in bood pressure, the bromide of ammonium will most probably give the required result.—*Glasgow Medical Journal*, Oct. 1882.

The Significance of Koch's Discovery.—In a recent letter to the Berlin Reichgesundheitsamte, Prof. Billroth discussed some of the practical aspects of Koch's discovery. He pointed out how the accumulating knowledge of the coarser pathological relations of tubercle have led to the conviction that the discovery must shortly come, and he paid a tribute to the investigations of Villemin, as having constituted the first and greatest step in the discovery—the step of demonstrating that tubercle is inoculable. This proved its dependence on a transferable virus, although we are only now able to eliminate the possibility that the virus might be of simply chemical nature. The various degrees of individual proclivity to suffer, observed in man, render it very important to study the variations of proclivity which are observed in animals. As a rule, it appears that the carnivora are less susceptible than the vegetable feeders (an unpleasant fact, by the way, for vegetarians). In the case of man, the only safeguard is the normal unsuitability of the soil, apart from the existence of inherited fitness. But another reason why local tubercle often exists without general infection—why, for instance, scrofulous caries of a rib so often exists without a general infection—is due to mechanical conditions. At the periphery of such a tubercular focus, in a bone or a lymphatic gland, there is an induration which probably hinders the exit of the tubercular organism and its passage into the blood current. The necessity of a high temperature, such as that of the blood, for the growth of the organism, probably lessens very much the extent of the disease in man, since, if the germs could develop out of the body, they would probably be ubiquitous. While the discovery of Koch raises even into greater importance than before the inherited predisposition, it will probably lead to some modification of our views as to the influence of that predisposition. Cases may be due to infection which are regarded as the result of inheritance only. A consumptive mother, for instance, may infect a child through a pocket handkerchief; moreover, the germs may be received by eating the flesh of infected animals. Certainly the conclusions are sufficiently probable to make it incumbent on us to treat consumption as in a measure an infectious disease.—*Practitioner*, October, 1882.

New Method of Treatment of Hypertrophy of the Tonsils.—Prof. Moresco, of Cadix, read a paper before the Congress of Seville (*Revista de Med. y Cirurgia pratica*) in which he recommended the treatment of hypertrophy of the tonsils by interstitial injections of acetic acid: he reports two cases perfectly cured by this method. He gives the following as the advantages of his method:

1. Its facility of performance.
2. The impossibility of causing any serious results.
3. The gland preserves its functions.
4. It requires no interference with the patient's occupation.
5. It is absolutely painless.—*Rev. Mens. de Laryngol., d'Otol. et de Rhinol.*, Oct. 1, 1882.

Spontaneous Rupture of the Uterus.—M. Salin (*Sw. Läkare Sällsk. Förhandl.*) reports the case of a woman 33 years old who had already had one child, with normal labor. The last menstruation occurred in August, 1881. She was in good health throughout the whole pregnancy. On the 9th of March she had pains simulating labor-pains, but was yet able to work. The next day in the evening she was seized with severe pains, which became more intense after a rectal enema, and so continuous and violent that she moaned loudly and without ceasing. There was slight hemorrhage from the vagina. The pulse was small, 130 to 140. Temperature in rectum 38° C. The abdomen was distended and tender, tympantic in its upper part, and there was dulness in its lower part. Fœtal parts could be felt around the navel, but it was impossible to perform palpation in consequence of the great tenderness. The canal of the cervix was sufficiently open to admit the finger. Immediately within the os internum it came in contact with a large fœtal part. Death occurred on the third day.

The autopsy revealed a rupture of the uterus at the fundus, through which the fœtus had escaped into the peritoneal cavity, the membranes remaining unbroken. The fœtus was in the eighth month. It was at first supposed that the rupture was due to some change in the muscular structure of the uterus, but subsequent careful microscopic examination of the parts showed that no change whatever had taken place in the uterine muscular tissue.—*Louisville Medical News*, October 14, 1882.

Resection of the Long Bones.—Mr. Arthur Neve reports three cases of resection of the long bones,

and urges that when necrosis of a long bone is an accomplished fact, the surgeon should operate at the earliest possible period, as he will thus substitute rapid repair for slow separation, healthy granulation for sloughing and suppuration. He would urge that the removal should be thorough, even bold; the re-formation of a considerable portion being easier than the casting off of a small sequestrum. When this practice becomes general we shall, he believes, see fewer deaths from hectic, and text-books will discuss at less length the subject of amputation after necrosis.—*Indian Medical Gazette*, September 1, 1882.

A SIMPLE METHOD OF INTRODUCING MEDICINAL SUBSTANCES INTO THE MIDDLE EAR, AND OF MAKING APPLICATION TO THE NASAL MUCOUS MEMBRANE.—M. PURICELLI (*Rundschau*, No. 7, 1882) recommends, in order to retain substances in contact with the nasal mucous membrane, that the patient should pronounce the vowel A, at the same time throwing the head back and breathing through the mouth, thus preventing all communication between the nasal fossæ and pharynx.

If the patient pronounces R while a stream of air is forced through the nose, the liquid will penetrate to the middle ear.—*Rev. Mens. de Laryngol., d'Otol. et de Rhinol.*, October 1, 1882.

A NEW CAUSE FOR MERCURIAL POISONING.—Two cases having recently come under our notice in hospital practice of mercurialism in men employed in exhausting the little globes used in the incandescent system of electric lighting, we think a brief notice of the fact will be interesting, and may perhaps call forth more information from others. In each instance the gums were swollen, spongy, and tender, and there was salivation. The patients were employed in the same room, and both knew that mercury was the cause of their ailment. So far as we could gather from their account, the poisoning must have been due to mercurial vapor from the exhausting pumps, as no mercury was used except that contained in these pumps. From the statement of one of the patients we should infer that all those employed in the room would suffer from these symptoms, and have to give up the work in less than a year.—*Med. Times and Gazette*, October 7, 1882.

FIBROMATA AND CYSTO-FIBROMATA OF OVARY.—DR. H. A. COE draws the following deductions from a study of this subject:

1. Fibrous tumors may, and do, arise from the ovary, independent of the uterus or the other adnexa.

2. In structure these tumors are true fibromata, yet peculiarly rich in long spindle-cells, which closely resemble those of the normal stroma; hence,

3. These fibromata originate, not by a local change, but as the result of a general hyperplasia of the ovarian stroma. Moreover, there is nothing to show that this process is of an irritative, or inflammatory, character.

4. The resemblance between microscopic sections of ovarian and uterine fibroids is so close that the differential diagnosis is very difficult, if not impossible.

5. Cysto-fibromata of the ovary, like those of the uterus, are of secondary formation, and result from changes in previously solid tumors.

6. Such cysts probably arise from the so-called "geodes" or "gelatinous patches."

7. These "geodes" do not represent any form of degeneration at all, but are dilated connective-tissue spaces, filled with a coagulable serous fluid, resembling lymph.

8. The "geodes" are probably dilated lymph-spaces, which expand by reason of the accumulated fluid in their interiors—a condition due to a general stasis.

9. That *lymph-spaces* rather than *lymph-vessels* are the seat of these changes is evidenced by their irregular shape, intimate relation with the surrounding tissue, manner of dilatation, and absence of endothelial lining. But that the proper vessels may also dilate in like manner is not improbable. (Comp. the "Ampullæ" observed by Leopold.)

10. Simultaneously with the lymph-stasis, there often exists a disturbance of the blood circulation, giving rise to œdema, extravasation, and various local changes, but these are factors in the *subsequent growths*, *not* in the *origin* of a "geode."

11. Commencing cysts grow by increase of the contained lymph, by accessions of blood and serum from adjacent vessels, and by degeneration of the surrounding tissue.

12. At no time in its history does a cyst possess a proper wall, since what at first appears to be such is merely the surrounding fibrous basis of the tumor, condensed by long pressure. A cellular lining upon the apparent wall of a fully developed cyst (originating like those referred to in this paper) is certainly very rare in a young growth, and highly improbable in the case of one of advanced age.

13. The fluid found in these cavities has originally the properties of lymph, but becomes so changed by intermixture with other elements, that its examination for clinical purposes does not furnish positive results.

14. The *ultima causa* of dilatation of the lymph-channels and consequent cyst-formation in fibroid tumors is unknown. Clinical observations lead to the inference that, in many cases, the active influences are *within* the growth itself.—*Amer. Journ. of Obstet.*, October, 1882.

FORCED FEEDING.—Recognizing the value, and at the same time the inconvenience attending the employment of forced feeding by the method proposed by M. Debove, M. DUJARDIN-BEAUMETZ has been making a number of experiments looking towards an improvement in the methods employed. In the first place, he finds that it is not necessary that the tube should penetrate the stomach; all that is necessary is that the tube should enter the upper part of the œsophagus, when the food can be forced into the stomach by pressure and efforts at deglutition on the part of the patient. It is also advisable to use a smaller tube than that employed by M. Debove. He recommends the administration of fluids by means of hydrostatic pressure.—*L'Union Méd.*, September 17, 1882.

A NEW SIGN OF PREGNANCY.—In the first two months of pregnancy there exists no sign which can be called diagnostic; JORISENNE (*Arch. de Tocologie*, June, 1882) seems to furnish one. Long ago Graves formulated the law that in cardiac hypertrophy the radial pulsations remain constant, whatever the position of the body. Starting with the assumption that in pregnancy there exists an hypertrophy of the heart (and this assumption, if erroneous, will not affect J.'s results), he has found that, whilst in health there is a variation of from ten to twenty beats in the radial pulsation, according as the body is upright or horizontal, in pregnancy, no matter what the position, the beats number the same. J. has been able to diagnosticate pregnancy as early as the first month when no other sign except the missing of a menstrual period was present. When examining a patient for this sign, it is necessary to proceed with deliberation, first counting the radial for the space of fifteen seconds whilst the patient is standing, then sitting, and then reclining. The order may then be reversed, and uniformly the same number of beats will be recorded. J. promises an explanation of this phenomenon in a future paper.—*American Journal of Obstetrics*, October, 1882.

Case of Gastrostomy.—The patient recently operated on by Dr. Felizet is now convalescing, and the Paris correspondent of the *Lancet* gives the following account of the case. On September 10th, a young Swiss man, aged 19, was amusing the customers of the *café*, where he was employed, by introducing a long spoon, such as is used for stirring coffee when served in glasses, into the œsophagus, pushing it as far down as he could and then withdrawing it. The performance was brought to an abrupt ending by the spoon slipping out of his fingers and disappearing down the alimentary canal. The following morning he was seen at the hospital by M. Felizet. Palpation revealed the existence of a foreign body, which projected in the left hypochondrium. Pressure upon this spot was painful, and caused a pricking sensation below the liver. The patient complained also of a feeling of constriction in the epigastrium, of difficulty in breathing, and of a painful sensation with each movement of the diaphragm. There was a constant flow of saliva and mucus from the mouth. Opium and ice were given to allay the pain, but in spite of this no sleep could be obtained, and bilious vomiting set in. This symptom, together with the patient's anxiety and suffering, decided M. Felizet to operate. In order to lessen the chance of the escape of any liquids from the stomach into the peritoneum, and to manipulate the abdominal organs as little as possible, the following plan was devised: A small India-rubber tube was introduced through one nostril into the stomach. The outside extremity terminated in a Y-shaped branch, upon one division of which was a funnel, whilst the other was in communication by means of a tube with a recipient containing ether. To begin with, the stomach was washed out by pouring a solution of sodium bicarbonate into the funnel, and then depressing the end of the tube below the level of that organ, so as to act as a siphon. The patient was then brought under chloroform and the operation continued with antiseptic precautions. An incision was made seven centimetres long, parallel to and one and a half centimetres below the edge of the false ribs, extending from the line of hepatic dulness, three centimetres below and external to the xiphoid appendix, to a point on the left side on a level with the junction of the ninth and tenth costal cartilages. The sheath of the rectus, and some of its fibres were divided, and the peritoneum exposed. Hemorrhage having been entirely arrested by torsion and ligature, the recipient containing ether was plunged into a vessel of water at 60° Centigrade, and the stomach at once became distended by the vapor, and the peritoneum, being divided upon a director, protruded through the wound. Ten sutures in all were then made to fix the stomach to the abdominal wall, the ether being allowed to escape, in order to ascertain whether the juxtaposition of the surface was complete. One spot appearing defective, the stomach was distended again, and another suture inserted. An incision six centimetres in length was then made in the axis of the wound. After the vapor had escaped, the stomach was found to be perfectly clean and empty. The spoon was felt, lying transversely across the stomach with one end in the pylorus and the other in the greater curvature; it was then extracted without difficulty. After the operation the patient was kept under the influence of morphia by small hypodermic injections. Tea and rum were given as a drink, with small pieces of ice. Antiseptic dressings were applied. The after-effects of the operation were not serious. There was no fever or tenderness of the abdomen. The most distressing symptom was great thirst, but this was relieved most satisfactorily by enemata of cold water. Notwithstanding the dressings, the liquids swallowed passed through the wound. On the fourteenth day, a little milk was given, but this oozed through the dressings, and was not renewed. On the fifteenth some meat was tried, but caused uneasiness. On the first of October, a considerable portion of the wound had healed, and all that remains is a fistulous opening, closed by a pad. The patient eats meat, vegetables, and pastry.—*Lancet*, Oct. 7, 1882.

The Effects of Thread and Round Worms upon Children.—M. Archambault recently made some clinical remarks at the Hôpital des Infants Malades, Paris, on the effects produced by the *Oxyuris vermicularis* and the *Ascaris lumbricoides* in young children. He said one of the smallest and most curious worms, the presence of which causes so much trouble to young children, is undoubtedly in the so-called "thread-worm," the *Oxyuris vermicularis*. This helminthe has its abode in the lowest part of the rectum, just within the anus. It is the cause of a number of troubles, and of very severe itching, which is chiefly nocturnal, and therefore often characteristic of the presence of this particular worm. The itching is sometimes so severe as to make children cry; it prevents sleep, and so gives rise to extreme irritation, which may bring on convulsions. This worm is also met with occasionally in adults, and has, by the intolerable itching to which it gives rise, brought on a veritable condition of hypochondriacism. Another effect, in certain cases, is an inflammation of the rectal mucous membrane, accompanied with tenesmus and muco-sanguinolent stools. In female children the worms may find their way into the vagina, and so bring on a vulvitis, more or less intense, with secondary effects which are most undesirable. Thus, although the presence of these minute worms is not in itself dangerous, yet the secondary consequences may be really grave. Their treatment is as follows: Administer an enema, for five or six consecutive evenings, of lime-water; if this is not sufficient, add—as Dr. West advises—a little perchloride of iron, and the worms will be almost certainly destroyed. Or a mercurial suppository may be tried if the enemata do not succeed. It is very desirable that the enema be properly administered, and in sufficient quantity; it should pass up as far as, or even beyond, the sigmoid flexure, so as to dislodge any worms which may have crept up beyond their usual site. As regards the lumbrici, it may be said that they are harmless ("*asez innocents*"); it is only when very numerous that their presence becomes dangerous. M. Archambault was once called to see some children who had just arrived from Brazil, and who had been taken ill with convulsions, vomiting, and diarrhœa. Finding in the stools a number of these round worms, he ordered calomel and santonin. An immense number of worms was passed—"it would be no exaggeration to say that the three children in three days passed a hatful of these helminthes." There are so many other anthelmintics than those just mentioned, that the physician's chief difficulty is the *embarras du choix*.—*Medical Times and Gazette*, October 7, 1882.

The Rational Treatment of Anterior and Posterior Uterine Displacements.—At a recent meeting of the Dublin Obstetrical Society, Dr. A. V. Macan read a paper on this subject, of which the following are the conclusions:

1. The normal position of the uterus when the bladder is empty is one of anteflexion. Hence mechanical treatment of anteflexion is rarely called for, and if symptoms be present our efforts should generally be directed to the cure of the complications.

2. In retroflexions or versions the primary indication is to treat the displacement. In order to do this effectually we should place the uterus in a position of exag-

gerated anteversion, and then fix the cervix posteriorly by a pessary.

3. Hodge's pessary, or any other pessary used for the cure of retroflexion, when uncomplicated with adhesions, should act by fixing the cervix posteriorly, and not by pressing against the fundus and elevating it.

4. Versions are, so far, more serious than flexions, in that they are caused by rigidity of the uterine parenchyma, which is generally due to chronic metritis.

5. To make the results of the bimanual examination of any use for comparison with the results of other observers it must be made in the dorsal position, the bladder having been previously emptied.

6. A great deal of the confusion that exists about the treatment of anterior and posterior displacements originates in its being taken for granted that any treatment that is found suited to an anterior displacement must be equally suited to a posterior one, and *vice versa*.—*Dublin Journal of Medical Sciences*, July, 1882.

VASO-MOTOR PHYSIOLOGY.—The vaso-motor effects which are produced by faradic stimulation of the peripheral segment of the lingual nerve have been lately studied by M. VULPIAN. This stimulation is well known to cause a considerable dilatation of all the vessels of the corresponding half of the tongue in the region in which this nerve is distributed. The experiment is easily performed on a dog under the influence of morphia, or which has been curarized and subjected to artificial respiration. The mucous membrane in this region, and also on the corresponding side of the frænum, becomes bright red, and a similar change may sometimes be observed in the mucous membrane of the gum on the inner surface of the lower jaw near the canine and incisor teeth. The principal vein of this part of the tongue becomes turgescent, and the blood contained in it and its tributaries becomes bright in color, resembling that of arterial blood, while there is a corresponding rise in the temperature of the part. These phenomena are produced sometimes after the lingual artery has been tied, and even after the internal and external carotid arteries of that side have been tied just above their origin, and the carotid itself has been tied in the middle of the neck. Nor are they prevented even by the ligature of the common carotid and the vertebral. The effects are equally marked after the section of the vago-sympathetic trunk, and after excision of the superior cervical ganglion. When the circulation has been definitely arrested, as by the farado-puncture of the animal's head through the thoracic wall, the opposite half of the tongue becomes pale before that on which the lingual has been faradized. Thus the effect of the stimulation is opposed to the occurrence of the constriction of the vessels, which occurs throughout the body almost immediately after death. Another remarkable fact noted by Vulpian is that at the moment when the dilatation occurs, in consequence of the faradization of the nerve, there is a distinct contraction of the vessels on the opposite half of the tongue. It is not merely the result of the determination of blood from one-half of the tongue to the other, but is the effect of a distinct activity of the vaso-constrictor nerves, for there is a distinct darkening of the blood. This condition, however, does not last so long as the dilatation of the vessels on the faradized side. The latter may continue for ten minutes, while the former has disappeared in half a minute. This vaso-constriction appears to be reflex, for it is far less conspicuous if the vago-sympathetic trunk on that side has been previously divided. The lingual nerve seems thus to possess a certain amount of recurrent sensibility, which is manifested by this reflex action when the peripheral extremity of the divided nerves is stimulated. —*Lancet*, Oct. 7, 1882.

THE BACILLUS OF TUBERCULOSIS.—That defective ventilation, or, in other words, vitiated air, is one of the most, if not the most potent factor in the production of tuberculosis, is among the best-established facts of hygiene, however the actual relation may be explained. In the Biological Section of the meeting of the British Association for the Advancement of Science, MR. F. J. FARADAY read a paper entitled "Considerations arising from Koch's Discovery of the Bacillus of Tuberculosis," in which, after referring to the suggestions made by Dr. William Roberts in his address to the British Medical Association in 1877, that disease-germs might be "sports" from harmless saprophytes which had acquired a parasitic habit, and to Pasteur's observations on the decreasing virulence of specific disease-germs when kept in the presence of oxygen, he asked whether deprivation of oxygen might not play an important part in the development of the tubercle-bacillus out of comparatively innocent forms. Dr. Angus Smith has argued that putrefaction carried on in confined spaces, as sewers, may give rise to disease-germs—enteric, diphtheritic, etc.—which are not developed when the same process goes on in the open air and in rivers; and Mr. Faraday thought that analogous conditions might be found in the lungs of persons engaged in dusty trades, working in ill-ventilated rooms, or otherwise habitually respiring imperfectly. Innocuous germs inhaled into the lungs of such persons may there undergo successive cultures in the presence of a reduced amount of oxygen, and thus, in course of time, develop into the specific bacillus of tubercle, which may then be capable of establishing itself in the lungs of healthy persons, provided they be especially susceptible or possess feeble powers of resistance. The decrease in the mortality from phthisis in the army, following on improved ventilation of barracks, the benefit of as many hours as possible spent in the open air, of sea-voyages, and of iodine or carbolic inhalations in phthisis, all seem to lend support to the hypothesis.—*Medical Times and Gazette*, October 7, 1882.

DIPHTHERITIC PARALYSIS.—DR. HENRI LEROUX reports an unusual case of paralysis, consequent upon a comparatively mild case of diphtheria occurring in a boy aged fifteen years. After the angina had lasted a week paralysis of the soft palate was noticed, and a month later there was marked ataxy of both upper and lower limbs, but without paralysis and with no loss of sensibility—loss of coördination being the marked feature. The muscles acted well with the induced current, but the patella reflex was absent. Dr. Leroux believes that the condition could only be explained by some alteration in the nerve-centre for coördinate movements.—*Revue de Médecine*, September 10, 1882.

HYGIENE IN HOUSE WALLS.—MR. T. R. BAKER, in a paper read before the Am. Assoc. for Advancement of Science, "On the Permeability of the Linings of House Walls to Air," assumed that ordinary wall paper made the walls nearly air-tight. Hygienically considered, the walls of a house should be porous, like our clothing, so that our bodies can have through them, as also through our clothing, free intercourse with the external air Compact wall linings, even if their minute pores are open, greatly interfere with this intercourse; but if their pores are closed with water, as when the walls are damp, it is almost completely cut off; and such linings increase the dampness of walls by preventing their drying in wet weather. The prolonged dampness also prolongs other evils produced by damp walls; therefore wall papers and their substitutes should be condemned, and the old-fashioned whitewashed walls commended.—*Popular Science Monthly*, November, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, OCTOBER 28, 1882.

DEMENTIA PARALYTICA.

THE MEDICAL NEWS expressed the opinion, long in advance of the microscopical examination, that Guiteau presented the symptomatic type of dementia paralytica. The only alienist, so far as we are aware, who announced the same view was Dr. Folsom, of Boston. Under the overshadowing pretensions and loud declamation of the experts for the defence, the theory of reasoning mania, or, as they, with a fine sense of the effect of erudition, are delighted to entitle it *primäre Verrücktheit*, came to be held by all the followers of these noisy neurologists. As we have had something to say regarding the relation of such a mental condition to criminal responsibility before the law, it will be desirable to place before our readers the modern conception of this strange malady. Beside these circumstances, by which the present attention of physicians is directed to dementia paralytica, this malady deserves attentive study, because of the frequency of its occurrence, the sad complications to which it gives rise, and its gloomy termination.

Dementia paralytica is a term which correctly expresses the morbid complexus, consisting of mental failure with paralytic symptoms. It is more commonly known as "general paralysis of the insane," and from the pathological standpoint has been designated "diffused interstitial encephalitis." The morbid anatomy consists essentially in an atrophic degeneration of the gray and white substance, the initial change occurring in the walls of the capillaries and in the perivascular lymph spaces, and the final result being wasting of the brain. It is not now necessary to our purpose to enter with more particularity into the morbid anatomy, as we are more concerned with the symptomatic development.

One of the early symptoms, objectively regarded, is a hesitancy of speech, accompanied by tremors of the tongue and lips. Coincidently, or preceding the speech defects, changes in the character become manifest, such as irritability and a quarrelsome disposition, not in accordance with their former history. After this, expansive notions begin to be entertained and wild projects are undertaken. Or if melancholic, the same vast notions dominate, and their miseries are the most abject which have ever befallen men. In the further progress of these cases, attacks of wild excitement—of homicidal fury, for example—now and then occur. The physical failure proceeds apace with the mental. As the motor and mental centres of the hemispheres and the white matter undergo the granular and atrophic degeneration, the difficulties of speech continue, words are forgotten and omitted from the speech, the tongue and lips tremble more and more, and the paresis of the extremities gives rise to a peculiar, shambling gait. Inequalities of the pupils, impaired vision and hearing, excite hallucinations connected with these senses, which participate in the delusions of grandeur now uppermost in the feeble mind. Thus with a condition of dementia, and paralysis, most obvious to all, these unfortunates have an aspect of gratified vanity, feel equal in mental power to the greatest names in history, and have the strength of giants. If the ideas of melancholy predominate, the same contented expression, the same unprecedented misery, the same immensity of grief are expressed. Finally, the speech is unintelligible jargon, or a mere formless mumbling, the body is emaciated and paralyzed, and life is ultimately extinguished by respiratory paralysis and mechanical pneumonia, if not previously ended by some intercurrent disease which, fortunately enough, frequently happens.

Notwithstanding that dementia paralytica is often an inherited malady, it may be produced under conditions which determine cerebral exhaustion. For the benefit of those of our readers engaged in study or arduous mental toil of some kind, it may be stated that such subjects are not given to this malady. Besides heredity, the trinity of evil causes are venery, syphilis, and alcohol. If these combine with heredity, the danger of producing the malady is proportionally great. As regards heredity, dementia paralytica must be regarded as the offspring of the family of neuroses rather than as the transmission of a special malady. The neurotic constitution is one from which any form of nervous disorder may spring—the peculiar direction taken by the inherited tendency being determined by the conditions surrounding the subjects of the inheritance.

The timely recognition of dementia paralytica is

of the utmost importance, not so much from the therapeutical point of view as the moral and social. The condition of such subjects must be understood in time to prevent the outbreaks to which they are liable; to prevent the complications growing out of extravagant ideas and the waste of property; to prevent the family estrangements and miseries of atrophied or forgotten affections and family ties, and to obviate the various social and business troubles produced in the circle of a man's relations who has become the unfortunate victim of this terrible disease.

Thus far the treatment of this fell disease has not been successful. Rarely, cases convalesce and are restored finally to their families and to society. In many examples of the disease remissions take place very unexpectedly, and a cure seems about to result, but after a time the symptoms become more aggravated. These facts, however, should stimulate the profession to greater efforts to find a curative agent. A few years ago Dr. Crichton Browne, of the West Riding Asylum, announced some very promising results from the administration of physostigma, but they have not been confirmed by others. Phosphorus and cod-liver oil and the phosphites and phosphates have been used with apparently good effects. We are yet, however, far from a curative remedy, and hence he who contributes it will confer an immense boon on the human race.

THE CLINICAL TEACHING OF OBSTETRICS.

THE recent trouble created by the action of a member of the obstetrical staff of one of our large hospitals, in bringing into the amphitheatre a patient in labor, and delivering her with the aid of forceps in the presence of the class, illustrates very well the manner in which many excellent people are misled by sentiment in matters which should be viewed in the light of experience and of common sense.

Of course, there may be circumstances under which, in consequence of the condition of the woman, or on account of the surroundings of the lecture-room itself, such a procedure would be manifestly improper, and with these, either in this particular case or in general, we do not propose at present to concern ourselves. It may be taken for granted that they will be considered and respected by every careful and practised obstetrician.

With the view, however, which condemns such methods of teaching on account of the "exposure" and "humiliation" of the patient, we do decidedly and unequivocally take issue. Its advocates ignore, on the one hand, the usual condition and mental or moral tone of pauper patients, which, however much theoretical equality is preached, are unavoidable factors in all such cases; and, on the other hand, forget the great benefits, present and prospective, which accrue to the community from successful and practical clinical teaching.

It is a fact which every lecturer of experience can substantiate, that when the necessary exposure is made with delicacy, and only to the required extent; when the explanatory remarks bear directly upon the condition or process to be illustrated; and when due regard is had to the comfort and safety of the patient, the latter rarely objects to being the subject of a clinical lecture. This is true, not only of obstetrical, but of all other forms of clinical teaching. The patient with typhoid fever, whose abdomen is carefully examined; the patient with venereal trouble, who, brought before the class with covered face, is inspected or interrogated; the patient with lacerated perineum, who, etherized in another apartment, is operated upon in the clinic-room; none of these object, in the vast majority of instances, to the accompanying exposure, realizing, doubtless, the force of that professional instinct which extends to physicians and students alike, and which renders suffering humanity sexless and sacred.

Such patients in large numbers depend each year upon the charity of every great city, and the gratuitous labors of the most eminent medical men. It is but just that they should repay, so far as possible, the obligations under which they voluntarily place themselves. Clinical teaching—instruction given in the presence of the disease or of the process which is to be elucidated—has long since taken a front rank among the means of imparting medical knowledge, and has largely superseded the old didactic methods. To those colleges and hospitals, and to those localities where such teaching prevails, students are now coming in great numbers—literally in thousands—and add largely to their prestige, their renown, and their material wealth.

Among the multitude of women who suffer with the various ailments peculiar to their sex, a large proportion, perhaps the majority, can trace the causation of their troubles to some accident, delay, or abnormality of labor. It is true that parturition is a physiological process, but that only increases its importance by adding to its frequency as compared with pathological conditions. Certainly in our time, under the circumstances of modern civilization, it requires to be carefully and intelligently superintended or assisted. Every possible parent is directly interested in having the medical practitioners of the future thoroughly instructed in all its details and dangers. Whatever tends to this end tends to the relief of suffering, the prevention of disease, and the preservation of life among the women and infants of the present and of coming generations.

To allow a sentiment, praiseworthy in itself, but here misapplied and not participated in by those in

whose behalf it is evoked, to interfere with such a humanitarian work, is to substitute personal feeling or prejudice for that calm judgment, which, while strictly respecting all personal rights, keeps steadily in view the essential object of securing the greatest good for the greatest number.

In the case in question, Dr. Warder, one of the staff of the Philadelphia Hospital, having begun his morning clinic in the amphitheatre of that institution, on Wednesday, October 11th, was informed by his resident that a colored woman in the obstetrical ward had been in labor for nine hours, that the os was widely dilated, but that the head refused to engage, and was asked for instructions. He directed that she should be etherized, carefully covered, and brought on a stretcher to the clinic-room. This was done, the circumstances of the case were explained to the class, the forceps were applied, and the woman safely delivered and removed to the ward. She has since died of puerperal fever, but unfortunately such deaths are not uncommon in the obstetric wards, and no inference associating the circumstances of the delivery and the termination of the case is warranted.

The Hospital Committee of the Board of Guardians, a newly appointed and most excellent and efficient body, passed a resolution recommending to the Board the dismissal of Dr. Warder, on account of his action, but subsequently modified this, after receiving a unanimous protest against it from the Medical Staff, to a resolution of censure. This was submitted to the Board at their stated meeting, Monday, October 23d, and addresses were made by various members of the Medical Staff. It was clearly shown that no rule of the Board or of the staff forbade the procedure; that no additional risk had been incurred in either the removal or the exposure of the patient; that the application of the forceps was imperatively necessary; that puerperal fever had recently caused several deaths in the obstetric wards; and that the fatal termination of the case was clearly due to infection derived from the latter source. After this the resolution of censure was voted upon, and rejected by a vote of eight to four. In the light of all the circumstances and of the expert testimony, this action was so clearly right that it seemed unavoidable, but hospital boards are sometimes disappointing in these respects, and it is especially to be noticed and commended that two of the committee recommending the motion, convinced of its injustice by the arguments of the Medical Staff, were manly enough to vote against it

It may be said, in conclusion, that this case is by no means an exceptional one. It has been the custom for years in all the large hospitals and schools on the Continent to give this kind of instruction whenever possible. Scanzoni at Wurzburg, Martin at Berlin, Braun and Spaeth at Vienna, and Dubois at Paris, have demonstrated clinically the use of the forceps, version, craniotomy, and other obstetrical operations before large classes. In New York, Isaac Taylor and Fordyce Barker at Bellevue, and Gillette at the Charity Hospital, Reamy at Cincinnati, and White at Buffalo, have done likewise, and in the Philadelphia Hospital itself the late Dr. Parry, one of the most esteemed and lamented, and one of the most conservative of Philadelphia obstetricians, has used the same room for the same purpose. Dr. Warder himself on a previous occasion, and without censure, had delivered a woman in the amphitheatre. No rule of the Board or of the Medical Staff forbade it, and no evidence was offered that evil resulted from it.

We have already given the general reasons applicable to this as to all similar cases why such teaching is greatly to be desired by the profession, the community at large, and particularly by poor women, who, in truth, are the greatest gainers by it, as they are the greatest sufferers on account of its neglect.

POST-GRADUATE INSTRUCTION.

In a recent editorial based upon the proposed establishment of a school for the instruction of graduates in medicine, the *Medical Record* takes occasion to claim for New York, which it modestly alludes to as the "acknowledged medical centre," the priority in this kind of teaching, and then very ably and properly calls attention to the importance of the subject. The question of local pre-eminence, considered from a medical standpoint, may safely be dismissed as one not to be profitably discussed or satisfactorily solved. Possibly Philadelphia, with the oldest and largest medical schools of the country, with their long list of alumni who have attained world-wide celebrity; or Boston, with its time-honored University, among the first to adopt and to sustain at great pecuniary risk the more advanced methods of medical education, might be thought to have claims in this direction; but they speak for themselves.

Far be it from us to decry or in any way to depreciate the admirable colleges, distinguished teachers, and large clinical facilities which give to New York such advantages, for all forms of medical instruction. We are each of us interested directly and personally in any attempt to elevate the general standard of professional attainments in this country, and particularly in any effort which will enable the hundreds of practitioners who, having graduated with imperfect preparation for the heavy responsibilities of their profession, having had no experience in the use of instruments of precision, having possibly never listened to a heart-murmur or felt the

crepitus of a fractured bone, to supplement these deficiencies and to acquire at least the special knowledge which they have found themselves most in need of. Individual courses designed to furnish this kind of instruction have for a long time been given at Harvard, at Bellevue and other New York schools, and at the Jefferson Medical College and at the University of Pennsylvania. More than a year ago at the latter institution they were organized into a separate curriculum with special fees at a reduced rate and with the almost entire substitution of clinical for didactic teaching, and have been markedly successful. The "poly-clinic" which is about to be put in operation in New York differs only, as we understand it, in not being connected with any existing medical school, and is deserving of the warmest support and encouragement.

We can all afford, without regard to questions of locality or of priority, to further any enterprise which aims to place within the reach of every hard-worked physician an opportunity to improve himself with the least expenditure of time and money. Such men do not need or desire to sit again on the benches and listen to lectures upon general questions of medicine. They have discovered their weak points by hard experience, often distressing to themselves, sometimes disastrous to their patients, and are impelled to remedy them as much by a conscientious wish to be thorough and capable of doing the greatest good as by any other motive. In whatever part of the country and under whatever auspices, such enterprises, when conducted by competent men, should command the hearty sympathy of the profession.

VARIABILITY IN THE STRENGTH OF THE ACONITIAS OF COMMERCE.

IN the issue of Squibb's *Ephemeris* for September, we find an exhaustive research by the accomplished Editor, on the various kinds of aconitia to be found in commerce. He refers to four specimens: To an ordinary commercial specimen of unknown source; to two prepared by Merck, of Darmstadt, and one by Duquesnel. The last mentioned was the only crystallized preparation. The relative strength of these four specimens of aconitia, as compared with one grain of good aconite root in powder, is as follows:

One grain of the aconitia of unknown source, was equal to one grain of the powdered root; $\frac{1}{8}$ grain of Merck's ordinary aconitia is equal to one grain of the powdered root; $\frac{1}{83}$ of Merck's ordinary aconitia from *A. ferox* was equal to one grain of the powdered root; $\frac{1}{111}$ grain of crystallized aconitia was equal to one grain of powdered root.

The test recommended by Squibb is the physiological one of taste, which he regards as superior in delicacy and vastly more readily applied, than any chemical reaction. If a preparation of good aconite root is placed on the tongue, in a short time a peculiar sense of tingling and numbness is felt at or about the point of contact. By having solutions of definite strength to bulk, it is perfectly easy to apply this test with certainty. The quantity of the preparation necessary to produce the reaction, and the time in which it is developed, are the points to be compared. As a result of his investigation, he concludes that a "well-made fluid extract of aconite root, made by repercolation with alcohol alone, from good root, is the best and only preparation needed."

Squibb seems inclined to regard aconitia as the only alkaloid of *Aconitum napellus*. *Napelline*, which has lately been brought forward, as our readers will probably remember, is therefore a decomposition product produced by the splitting up of aconitia, during the process of extraction. The alkaloid, known as *Pseudaconitine*, obtained from *Aconitum ferox*, is different from the aconitia of *A. napellus*. These facts afford additional reason for adopting the suggestion of Squibb, to obtain for medical uses a well-made tincture or fluid extract of good aconite root.

SANITARY INSPECTION OF SEA-SIDE RESORTS.

"IN time of peace prepare for war" is an adage of the statesman, and the New Jersey Board of Health evidently believe it to be equally true in sanitation. Accordingly, they have begun now a sanitary inspection of the sea-side resorts which line almost the entire Atlantic coast of the State.

None too early have they done so. Long Branch, Seabright, Ocean Grove, and other summer resorts have obtained unenviable notoriety during the past year by their cases of typhoid and typho-malarial fevers. The soil of the whole Atlantic border of the State predisposes to a bad sanitary condition. It is so porous that almost so soon as the population of any mushroom town has grown big enough to have a post-office, the lots have shrunk to a size that endangers the well-water either from the owner's own or from his neighbor's privy-well. Even if this be not the case, the soil itself soon becomes so saturated with decaying filth that it is a serious source of danger. Until, then, a water supply by expensive "water works" and a disposal of sewage by a well-planned sewerage system are both in operation, every year must add to the dangers to health and life. All this too, be it observed, in addition to the many defects in the drainage of the individual mammoth hotels—defects which, even in such wholesome spots as the White Mountains, may develop typhoid and other equally dreaded forms of disease.

Every summer Philadelphia and New York pour

forth upon the Jersey coast an almost heedless multitude, like the locusts of Egypt for numbers, and each year the crowd is increasing, both in number and in length of sojourn. The Board of Health, acting in the interest of both the hosts and their patrons, have begun a needed work. Not one of these resorts should escape a thorough overhauling, both in the general municipal hygiene and in the local arrangements. The summer visitor is worth more to New Jersey than any other crop. Let heed be taken lest the crop fail.

While on New Jersey matters, let us call attention also to the spurious economy of the town of Paterson. Following a smallpox "scare," the town established free vaccination, as was most judicious; but instead of procuring a reliable virus, they obtained it from a very doubtful source Fortunately, no bad virus seems to have been furnished, but only a worthless article. But none the less will it probably cost not a few lives since smallpox has again appeared, and it will involve more expense than if vaccination had been well done at first, for now it has all to be done over again.

SOCIETY PROCEEDINGS.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Tenth Annual Session, held at Indianapolis, October 17, 18, and 19, 1882.

The Tenth Annual Session of the American Public Health Association at Indianapolis, Ind., was opened on the morning of October 17th, the President, Prof. R. C. Kedzie, of Lansing, Mich., being in the chair. About sixty members were present. After prayer by Rev. E. H. Bradley, the first business brought before the Association was a report presented by Dr. Gihon, of the Navy, from the Committee on

A NATIONAL MUSEUM OF HYGIENE,

It announced the establishment of a sanitary museum at Washington, under the direction of the Surgeon-General of the Navy, who obtained from Congress an appropriation of $7500 for that purpose, and recommended the appointment of a permanent Committee on the National Museum of Hygiene, to be the medium of communication between the Surgeon-General of the Navy and the Association. In the course of the report it was stated that it was not proposed to make the library a large collection of unread books, the only use of which would be the production of a huge catalogue. Upon this Dr. Billings remarked that the language seemed uncalled for, and had probably been used inadvertently. He hoped that in forming the proposed museum and library it would not be considered expedient to attack other departments of the Government, and especially the Library of the Army-Medical Department. The Library of the Surgeon-General's office at Washington already possessed all books and journals pertaining to Hygiene, but it would be very glad to see other libraries do the same. Upon this the offensive clause was at once stricken out by Dr. Gihon, and the report thus amended passed without dissent.

The next business was action upon several

AMENDMENTS TO THE CONSTITUTION,

which had been proposed at previous meetings. The first of these amendments provided for the division of members of the Association into active and associate members. The active members form the permanent body of the Association, and are to be chosen with special reference to their acknowledged interest in sanitary science, and to the practical applications of the same. The associate members were to be elected only for the year for which they are proposed, and to have all the privileges and publications of the Association, except that they are not entitled to vote.

Dr. Billings moved the passage of this amendment, saying that it was the result of careful deliberation among the older members of the body, and was believed to be essential to its future prosperity and success. Under the constitution, only those known as sanitarians could be admitted to membership, and it was not desirable that this should be changed, if the dignity and influence of the Association were to be preserved.

The first paper on the day's programme was that by Dr. Horatio R. Storer, of Newport, R. I., on

THE NEWPORT (EDINBURGH) SYSTEM OF SANITARY PROTECTION.

Dr. Storer briefly refers to the first conception of the new principle in sanitation termed "protection," which is based on individual organization made collective upon the principle of mutual life insurance, by Prof. Fleming Jenkin, of the University of Edinburgh, in April, 1878, and its immediate introduction into this country, at Newport, R. I., in November of the same year. Four years have now elapsed since the commencement of the Newport experiment, now such no longer. The system had early been successfully copied at Lynn, Mass., and subsequently at Trenton, N. J., Brooklyn, Savannah, Montreal, and other cities and towns. The Newport Association from the outset had labored first, foremost, and all the time for a city board of health, distinct from the aldermen. As yet its efforts had been unsuccessful, but the local public sentiment had been so enlightened and elevated, through constant agitation of the subject, and so great a moral pressure had been brought to bear upon the city from without, through the daily and professional press of the whole country, that not only was the special change that had been desired now close at hand, but, with clearer views of the public need, there had arisen a demand for other municipal progress, general and far-reaching in its scope.

Detail was then given of certain measures employed by the Association for insuring complete inspection of the houses occupied by permanent residents and transient visitors, and a digest of the public and private work accomplished during the past year. The charter of the Association is also given as a guide to similar bodies, it having already proved a protection against annoying suits at law. There is also appended in addition the report rendered to the Association upon the dangers of impure ice, by Professors Pumpelly and Hills, of Harvard University, and Dr. Storer, which has already received from the greatest of living English chemists, Mr. E. Frankland, of London, his unqualified praise. The source of the whole ice supply of Newport was found polluted by the overflow of several cesspools, and the experiments made by the chairman of the committee proved most conclusively that during the congelation of water its impurities are collected together, concentrated and intensified in the resulting ice. The association therefore enjoined upon the Newport Ice Company to either protect its pond or discon-

tinue using it. The former course was very sensibly adopted, by the construction of an expensive intercepting sewer, to the very great advantage and enhanced safety of the whole city of Newport.

DR. THAD. M. STEVENS, of Indianapolis, read a paper on

THE HISTORY OF HEALTH WORK IN INDIANA TO DATE,

in which the organization of the State Board of Health was set forth.

The discussion of the papers was very brief, and at 2 o'clock the Association adjourned to 7.30.

EVENING SESSION.—The Association reassembled, and received addresses of welcome from Mayor Grubb and Governor Porter, after which the President, DR. R. C. KEDZIE, delivered the

ANNUAL ADDRESS.

Members of the American Public Health Association: Once more we meet in annual council to consider questions which intimately concern the weal—the literal wealth—of our common humanity. In this council political lines and sectarian differences are swept aside like the foam on some mighty river, while the current of the forces which tend to purity, to safety, to health and life of all who are exposed to pain, to sickness and death, moves on with the unswerving and resistless sweep of destiny. We come from different States and widely-separated communities, each with his individual ideas, cares, and anxieties; but all with a common purpose to subordinate personal preferences to the general good, and above and beyond all selfish interests, to place the welfare of the community.

But as we thus meet with clasp of hands and words of mutual welcome, there is a shadow on your faces as the thought continually obtrudes itself that we are not all here. Since we last met death has taken from us one of our brightest and best beloved—our President of one year ago. You had all observed with unspeakable pain the evidence that to him life was not to be long; yet when the news of his sudden death came, it brought a shock to us all. While his life was short, as measured by years, it was long when measured by the deeds done for the good of man. "That life is long which fills life's end," and who of us can show a brighter record of unselfish devotion to well-being of his race, than Dr. Charles B. White? As physician in the Crescent City, as President of the Louisiana State Board of Health, as Medical Director of the Auxiliary Sanitary Association of New Orleans, a city presenting more difficult problems to the sanitarian than any city within our borders; and, finally, as President of this Association, Dr. White manifested everywhere and at all times a devotion to the public weal, and a capacity to promote its interests, excelled by none.

Sanitary science includes everything that can prevent disease and thus promote the public health. The public health is not an entity apart and by itself, but is the aggregate of the health of the individuals of a community. Any means that will promote the public health, will correspondingly increase the well-being of the largest number of individuals. If the sanitarian is working for noble ends by unselfish means, let him not therefore suppose that he will be exempt from the imputation of sordid motives, or that he will at once be hailed as the benefactor of his race. Human nature resents the assumption of moral excellence. "Every man's work shall be tried by fire of what sort it is," and he who acts from motives that seem a rebuke to selfishness, will be subjected to the ordeal of a furnace heated sevenfold.

Dr. Kedzie then took up the question, Does sanitary science secure longevity, not by enlargement, but by the attenuation of life?

A French writer has wittily said, "The health which is secured only by constant watchfulness is itself a kind of disease." There is here a happy combination of wit and error which is characteristic of French genius, but the statement itself is only a travesty of preventive medicine. The man that removes known causes of sickness and death exhibits the same forethought on these vital subjects that is demanded in every successful calling in life. A prudent man will give to the protection of health a care corresponding to that bestowed upon the preservation of property, or any other good he may acquire or inherit; only as the posessions are of less value than life and health, and are valueless in their absence, he will give more heed to things of highest importance. "Wisdom giveth life," said the wisest of earth, and he is not to be accused of folly who prizes this gift of wisdom. The man who builds his house in such a way as to prevent the possibility of "a defective flue," and thus secures his household against nine-tenths of the alleged causes of fires, is not to be classed with the fellow who, mousing around at untimely hours, awakens you with the exasperating inquiry, "Don't you smell fire?" The man who prevents disease is not to be mistaken for the valetudinarian who spends life in dodging death.

When we look at the lower forms of life we find that under the guiding and fostering hand of man they have reached a degree of development and attained a length of life not reached in their natural state. This has been well pointed out by Dr. Jarvis in his article on "The Political Economy of Health."

Human life, as at present seen, is not like a goblet filled to the brim, to which any addition is to be compared to piling fluid upon fluid in unstable equilibrium, liable to sudden overflow, all the more imminent as the accumulation proceeds. It is rather a half-filled bucket whose staves are so imperfectly compressed by the loose-fitting hoops that leakage—not overflow—prevents further accumulation. The sanitarian seeks to tighten the hoops, and thus secure filling to the normal capacity, so that man may fill the measure of his days, and not be defrauded of the precious years of his earthly heritage.

Among the causes for hopefulness for the immediate future, I name the following:

1. Extension of the knowledge of the causes of zymotic diseases, such as charbon (or splenic fever) and chicken cholera in domestic animals, and of diphtheria in human kind. All infectious and contagious diseases must soon be brought into the same category, when we shall know and identify the specific cause.

2. The prevention of these diseases by extension of the method of inoculation. This has been done in some diseases of domestic animals. If by similar means measles, diphtheria, and scarlet fever can thus be brought under control, and priceless childhood be rescued from this trinity of woe, how many a Rachel, now weeping beside her childless cradle, will be comforted!

3. The discovery of the bacillus, which is the cause of consumption, by Dr. Koch, of Berlin, marks an epoch in the history of medicine. Tubercular consumption has been the opprobrium of medicine. It is the remorseless destroyer of our race, being the cause of one-seventh of the deaths of our race, and of one-third of the deaths in the active period of adult life. It has sown the earth with untimely graves. It is yet too early to say how much immediate benefit shall spring from this capital discovery, but any means which shall bring within our control, even remotely, this fell destroyer of our race, is full of promise. If science shall stretch forth only the hand of prevention, what a boon to our kind! If it shall finally reach forth the hand of healing and guard mankind from consumption

as effectually as she has saved us from smallpox, or the lower animals from splenic fever, what a shadow will be lifted from the face of our common humanity!

4. Another element of hopefulness is the world-wide interest now taken in questions of public health. In centuries past, history tells us of the gathering of œcumenical councils, where met the representatives from all the civilized world to consult on questions of momentous religious interest, and to decide upon the great affairs of the church. Modern times see the gathering of similar councils of equally widespread constituency to consult about questions of temporal salvation and conservation of the public health. What would the seventeenth century have thought of a world's health congress, with representatives from every nationality in Europe and America. The warlike races are beginning to ponder the question of Christ: "Is it lawful to save life or to kill?" and to suspect that to kill is only half of the duty of a great nation, and that to save life is nearly as important. It is certain that national bigotry has been compelled to give place to amicable restrictions and concert of action for restraining disease. The saviours of our race shall yet be as honored as its destroyers have been.

5. In our land the sky is bright with promise, the organization of so many State boards of health—and we greet with hearty welcome Indiana, who has lately joined this sisterhood of the order of mercy—so many State boards have been organized that now we count up to see how many States have no boards, instead of enumerating the number that have. The work of these boards has been silent as the light, but quickening as the sunbeams. Some State boards, like Illinois and West Virginia—may their tribe increase—have cleaned out the profane and ignorant crew who, for petty gain, would experiment and trade on the lives and health of men. The homes and the bedsides of the weak and suffering have been saved from the clutches of these harpies. Blessings on the law which holds the benignant shield of its protection over the suffering and sorrowing, shielding them alike from ignorant greed and artful cunning. The work done by all these State boards, in investigations of the relations of remote causes to the public health—moisture and dryness, heat and cold, ozone and electrical conditions, etc.—the dissemination of information on all these questions relating to public health, so that when some terrible epidemic fills a village with wild wailing, high above the din and clamor of grief rises a clear voice, demanding, in tones not to be silenced, who will tell us the cause of this, and how to remove it? So also the sanitary conventions enlist all parties in the discussion of questions relating to public health, and spread information on these literally vital questions—in short, enlist humanity in a crusade against disease, bearing aloft no blood-red battle-flag, but lifting up the banner with the white cross of health!

Other organizations in the interest of health without number have been formed—required by law, or voluntary in their organization, the jurisdiction confined to a city or village, or including a large territory. Some of these organizations have effected wonderful results, and their combined influence is beyond human calculation. Foremost in these voluntary organizations I place the Sanitary Council of the Mississippi Valley. Without funds or patronage, without authority to command a single individual, with no power save the high purpose and courage to do good, and the confidence which such qualities inspire, the council put down shotgun quarantine, and for the past two years has kept the valley of the Mississippi open to commerce and travel, but closed against pestilence.

Let us now turn the leaf and look at some of the discouragements.

1. There is so much to be done and so few to do. Lift up your eyes to the redemption of the world from avoidable disease and premature death, and behold the fields are white for the harvest, but the laborers are so few.

2. A few who profess to be reapers are wasters. They care little for the precious grain, but want the straw to make themselves a nest. With great volubility they point out the fact that the largest part of the harvest is straw, and insist that to waste so much good straw which will make them a nice warm bed, merely to save a little grain, is unconstitutional waste, and an invasion of reserved rights. This was to be expected. Eden had its serpent with his plausible suggestions of profit to be secured by wrong-doing. Christ found His Judas, whose eye was ever on the purse, and our own revolution had its Benedict Arnold, willing to sell out struggling right for personal profit.

3. A third cause of discouragement is found in what may be called the hostile indifference of Congress and the executive to the National Board of Health. The American Public Health Association and the Sanitary Council of the Mississippi Valley were active in securing the organization of the National Board of Health. Both the Association and the Council are firm believers in the need—aye, the vital necessity—for a National Board of Health, whose jurisdiction shall be conterminous with the national boundaries, backed by national authority and sustained by the national purse in its holy warfare upon communicable and preventable disease. State's rights may glitter and splutter upon trivial questions of politics, but disease will not pause at State lines nor halt at municipal boundaries. When destruction takes on winged form and comes floating on the very winds to lay waste our heritage, then we want some power whose jurisdiction shall be as wide-reaching as the wings of the destroyer, and shall command every force and resource requisite to withstand the invading foe. Look at the situation. Smallpox has been pouring in with the flood of European immigration, and but for the timely action of the National Board of Health, and the efficient aid of a few State boards of health, the Northwest would have been one widespread hospital for smallpox, and the commerce of this vast region closed for a time. Yellow fever has been flickering like the baleful fires of the tomb along our Gulf borders, and lately has blazed up into an epidemic, destroying life, wasting large communities with sickness, and crippling the commerce of our gulf coast—inflicting a money loss exceeding tenfold the entire cost of the National Board of Health, to say nothing of the suffering and death thus entailed.

When we look to the future the prospect is not reassuring. The same destructive agencies will continue to work in the future as they have in the past. When we turn our eyes to the East we find additional cause for apprehension. Cholera has roused up from its lair in the jungles of India; is now laying waste the islands of the Indian Ocean, and will soon start on its sweep westward to lay waste Europe, to charge across the stormy Atlantic, and, like its predecessors, to die out in the valley of the St. Lawrence or along the banks of the Mississippi. Is this a time to withdraw the watchmen who guard the public safety, to call in our trusty picket line, and hope to meet the destroyer with the *fulmen brutum* of States' rights, or the guerilla warfare of isolated municipal action.

The painful conviction abides with us that a fearful blunder has been made in thus crippling the National Board of Health, and that we have been guilty of the folly of changing front in presence of the foe.

We thus see that light and shadow alternately flit

across our landscape, but the light grows stronger and the shadow less sombre. But we should remember that, whether in sunshine or in shade, the landscape still remains. In health or in sickness, in pleasure or in pain, the race moves on forever, keeping even step with the noiseless footfalls of time; that whatever we may contribute towards improving the condition of our race will be a permanent addition to the welfare of our kind, while our errors and mistakes, like dead leaves and useless chaff, will be mercifully buried in our graves. We are now painfully and wearily sowing the seed, but the generations to follow us shall reap the joyful harvest. Because we are only sowers, and because we shall never thrust in the sickle of the reaper, let us be only the more careful to scatter precious seed. Though our eyes shall never behold the sheaves of that far-off summer-time, our ears may yet catch the echoes of their harvest song. Listen to the refrain: "There shall be no more thence an infant of days; nor an old man that hath not filled his days, for the child shall die an hundred years old." In the ages past how large a proportion of human beings were ushered into existence whose life was measured not by years or months, but were literally infants of days. By the advancement of sanitary science and the stricter enforcement of sanitary law, the proportion of "infant of days" has been steadily diminished, and a constantly increasing number pass on into adult life. Year by year and age by age a smaller number die in infancy and a larger proportion pass forward to productive manhood. With wider knowledge and more general enforcement of sanitary law, this diminution of infant mortality and expansion of human life will go forward with ever-increasing momentum till life will attain its normal limits, and every child shall reach his hundred years. Not only will life be extended, but the long life will be full of joyful activities, and man shall fill his days. For this we toil and hope. God speed the day!

OCTOBER 18TH.—SECOND DAY.

On motion of the Executive Committee about one hundred and fifty persons were duly elected to active and associate membership.

A resolution for a standing committee of five on the National Museum of Hygiene was adopted.

DR. RAUCH, of Illinois, read a paper entitled

OBSERVATIONS IN REGARD TO THE RELATIVE SIZE OF THE LIVER AND SPEEN, AND THE NORMAL TEMPERATURE IN TEXAS CATTLE,

by DR. JOSEPH R. SMITH, Surgeon United States Army, and Medical Director of the Department of Texas. The paper was a long and elaborate one, and, was mostly taken up with the record of exact observations. The author thinks no danger to northern cattle can result from the transportation of Texas cattle, apparently healthy at the commencement of their journey north.

Remarks were made by Drs. Becker, Ryan, and Hunt. Their idea seemed to be that Texas cattle were peculiarly subject to Northern climatic influences, malarial and otherwise, diseases being developed which had shown no evidence of their existence in Texas.

DR. ELISHA HARRIS, Secretary of the New York State Board of Health, offered a resolution instructing the Committee on Cattle Diseases to consider the pathological and etiological conditions of Texas cattle disease. Drs. Smith and Harris were added to the Committee on Cattle Diseases, and Dr. Smith was requested to continue his investigations.

DR. E. E. HOLMAN, of Chicago, read a paper on

STOCK TRANSPORTATION.

He stated that stock in transit are often allowed to go one hundred hours without food and water. Another species of cruelty is practised in the crowding of sheep or hogs into cars with cattle, to fill up the interstices between the legs of the latter. The story of the sickening cruelties practised on animals in transportation was almost incredible. The writer thought it almost, if not quite as bad, to kill these bruised, maimed and crippled animals, for food, as to use those that had themselves died under such treatment. No amount of cooking is adequate to restore diseased tissue to health. The speaker recommended the use of stock-cars which will allow the stock to lie down, and also the use of refrigerator-cars to transport meats. The greatest point to be gained is the education of the consumer up to the point of demanding healthy meat.

DR. T. P. WILSON, of Ann Arbor, Mich., read a paper on

LIFE ON WHEELS.

He estimated that from 1,000,000 to 1,500,000 people are on the cars in this country daily. Railroad travel is not necessarily perilous and uncomfortable. The first want is fresh air. Fifty or sixty persons in a car exhaust the oxygen in a car in a few minutes. Sleeping-cars are a little worse, and the lower berths are worst of all. The heating arrangements are defective, and the drinking water from tanks in cars is bad.

DR. A. N. BELL, of Brooklyn, corroborated the author's statement in regard to the filthy and impure water used on trains. He thought the great reform needed in cars was to abolish the upholstered furniture. The heavy plush seat-covers and heavy woollen curtains catch and retain seeds of contagion.

DR. MILLS, of Port Huron, criticised the combination of water tank and water closet used on some cars.

DR. ELISHA HARRIS, Secretary of the State Board of Health of New York, read a statement of the work of the Board.

DR. JAMES E. REEVES, Secretary of the West Virginia State Board of Health, made a statement of sanitary progress in that State, claiming that it possessed one of the most perfect sanitary systems in the Union. The Board does not confine itself to sanitary work, but also controls and regulates the practice of medicine in the State. There are established three classes of physicians: First, those who are graduates of reputable medical colleges; second, those who have been engaged in continuous practice for ten years; third, those who come before the Board for examination. It is to the medical profession that the people must look for sanitary reform, and only by such very great authority as is given the West Virginia State Board, can such reform be made effective.

DR. RAUCH, Secretary of the State Board of Health of Illinois, cheerfully allowed that the work of the West Virginia Board of Health was the best in the Union.

DR. SAMUEL W. ABBOTT, of Wakefield, Mass., then read the following paper on the

USES AND ABUSES OF ANIMAL VACCINATION.

The author's object was to present for consideration the advantages which are offered by animal vaccination in preference to the older, and, until the beginning of the past decade, the more common method of vaccination by humanized virus. He also referred to some of the abuses to which animal vaccination is liable.

Until the occurrence of the great epidemic of smallpox in 1871–1873, throughout the United States, vaccination had been performed almost exclusively with humanized virus. There were some few exceptions. During the late war of the rebellion, large quantities of crusts were supplied to the surgeons of the army for the purpose of vaccinating soldiers, these crusts having been obtained by the process of retrovaccination, *i. e.*, the vaccination of cattle with humanized lymph. This

practice had the sanction of the medical department of the United States Army, and was doubtless as efficient as any vaccination with crusts. But this mode of propagation failed to win public confidence, doubtless in consequence of a belief in the transmission of human diseases through the cow to man. I am not aware, however, that any facts have ever been adduced to substantiate such a hypothesis. This process of retro-vaccination has also been practised to a considerable extent in other countries, as in Bavaria, from 1818 to 1825, and also in the island of Trinidad.

Humanized virus has been the rule from the days of Jenner until the successful propagation of virus from the well-known case of cowpox which occurred at Beaugency, France, in 1866. The introduction of this practice into America was mainly due to the efforts of Dr. Martin, of Roxbury, Mass., who imported animal virus in 1870 and began the successful propagation of vaccine virus from that time in an uninterrupted series of animals. A new era in the mode of virus production was thus introduced.

In early years vaccine virus was obtained very much after the manner in which our ancestors occasionally procured fire for household purposes before the advent of friction matches. Application was often made to some fortunate neighbor who had carefully preserved his burning coals from day to day. So the country physician often drove away to his professional brother's office in a neighboring village, who had also kept alive his stock of virus by arm-to-arm vaccination of infants, or perhaps by means of a bit of crust carefully stowed away in a corner of his office-desk for future use.

Gratuitous distribution of virus was a common event at the meetings of district or county medical societies. Within the past decade the entire process of vaccination and the general supply of virus in the United States has become revolutionized in consequence of the rapid increase of population, the immigration of hordes of unvaccinated people, the introduction of animal vaccination, and various minor causes, so that, what was once a matter of gratuity or accommodation, has become a regular traffic; the physician purchasing his virus directly from the propagator or from some middle man, usually a druggist, who, to use a technical term, "carries" the article as a part of his stock.

It is safe to say that nine-tenths of all the virus employed in the United States at present is obtained in this manner, by purchase, and also that at least as large a proportion is of animal origin.

Hence, in accordance with the usual laws of supply and demand, certain parties, usually physicians, have undertaken to furnish virus in such quantities as may be required, by the constant propagation of the same in and through bovine animals, purchased or hired for the purpose.

The practice of animal vaccination is reasonable, and is preferable to any other mode. It is also a matter of the highest importance that every safeguard should be afforded, both by legislation and by private practice, to render its performance perfectly safe and efficient.

Reasons for its use:

The impossibility of obtaining a supply of virus from humanized sources in sufficient quantity and with requisite promptness for use in times of epidemic.

The possibility of the transmission of other diseases besides vaccinia, through the inoculation of human vaccine lymph, was for a long time denied by the medical profession, with but few exceptions. Then came a period of doubt and of hot discussion, but at the present day the evidence of such a possibility is too overwhelming to admit of reasonable denial. The advocates of humanized virus are divided in their opinion upon this subject, but the careful instructions which all enjoin as to the selection of healthy vaccinifers, and also to the importance of cleanliness, are only too certain evidence of an unwilling admission of the fact.

It has been alleged by advocates of humanized virus that there is no danger of syphilitic inoculation if blood is not conveyed together with the lymph or serum. But who is to decide as to the presence or absence of blood, and what is the so-called vaccine lymph itself but a portion of the blood, plus the unknown quantity called virus? Vaccine lymph may be colored in varying degrees, from a deep red down to an almost colorless fluid, in which no trace of blood may be visible to the eye. The trained microscopist may, nevertheless, find blood corpuscles quite abundant. But it is impossible to find a microscopist at one's elbow for immediate service at every vaccination.

The introduction of vaccination with direct bovine virus obviates the whole objection, and also disarms the opponents of vaccination, in general, of the most potent argument thus far urged by them.

Transmission of Bovine Diseases.—The hypothesis of the transmission of bovine diseases has been urged. If this doctrine were tenable, facts would have been adduced in its support, for the vaccinations with bovine virus in the United States alone, within the past ten years, may be estimated at not less than three or four millions.

A careful search in the records of vaccination and of anti-vaccination literature, fails to reveal a single authentic case of transmission of genuine bovine disease, other than vaccinia itself.

In regard to the matter of *efficiency* or potency of bovine virus, I am aware that a certain superiority has been claimed for it, over humanized virus, and while I have not observed any preëminence of this sort, I can confidently assert, after an experience of twenty years (ten with humanized and ten with bovine), that the action of bovine virus is at least of equal potency, and also identical in its mode of operation.

The results of observations recorded in the medical journals during the past year or more, are widely dissimilar. A few observers record a superior efficiency for bovine virus, a greater potency, and a larger per cent. of effective vaccinations. A larger number still record an inferior potency, and a smaller ratio of effective vaccinations. In some cases a total failure is recorded. I regret to notice that nearly all of these observations show a total disregard of the essential conditions of scientific observation. All such observations should be conducted under conditions which admit of no possible doubt. On the contrary, one observer reports his virus as purchased from a reputable dealer, another from a reliable druggist. Another observer does not state whether vaccinations were primary or secondary. Scarcely any observer could state the exact age of the virus which he used (a matter of the greatest importance), and in some instances could not confidently affirm that he was using vaccine virus at all, instead of some fictitious product.

On the contrary, the testimony of physicians who vaccinate with virus of their own propagation is uniformly that of a high ratio of success, usually from 95 to 99 per cent. in primary cases. The reasons are obvious—the propagator of virus knows its source and its age, and hence attains a uniformly high rate of success in vaccination.

The Importance of a Perfectly Pure Standard of Animal Virus.—Care is necessary in the selection of animals. They should be healthy, and in good condition as to flesh. They should be well fed and clean, and should be housed in dry, clean, airy and comfortable stables, and should be free from disease of every sort, including cutaneous eruptions.

The age of the animal is a matter of importance. My own preference is in favor of adult cows. In earlier years I made this a matter of experiment, and vaccinated all ages from calves of a week old to adults of a dozen years. From these experiments I concluded that animals of a gentle disposition, in a good condition of flesh, with a rather thin hide, and from three to six years of age, yielded the best results.

The sex is also important. Virus will take as readily in bulls and oxen as in cows, and the vesicle may present as typical an appearance, and by actual experiment I find the virus equally efficient. The difficulty lies in the thickness of hide. This quality renders it almost impossible to obtain a sufficient flow of lymph for practical use.

Analogy would lead us to employ females. So far as I can learn by observation and inquiry, spontaneous cowpox (if the term be a correct one) occurs only in cows, and usually in those that are giving milk. Of at least twenty cases of natural cow-pox which I have inspected during the past eleven years, all occurred in milch cows, and I find this statement confirmed by the observations of intelligent farmers and drovers of cattle. The theory that natural cowpox is a rare disease has no foundation in fact, and only gives evidence of a neglect of careful observation of the habits of animals. One would suppose, from the extensive run of the term "Beaugency," that such a case is almost unknown in America, a land abounding in cattle, and annually exporting thousands to foreign ports.

Adulterations, Dilutions, and other Frauds.—The immense demand for virus created by the last two epidemics of smallpox which have befallen this country, has brought with it more or less of the frauds which are liable to all traffic, either in food, drugs, or other similar articles.

It is important, therefore, that adequate protection be provided in the case of vaccine virus, by the use of which so many of our population are protected from loathsome pestilence. Such protection should warrant purity above all things else.

Vaccine virus is collected for use and offered for sale in various forms.

1. Dried lymph collected and preserved for use upon ivory or bone points, bits of goose-quill, glass, and pieces of silk or thread. The latter are but little used.

The points and quills have been used largely throughout the United States for several years, and are the safest and most convenient forms for general use. These points, either of bone or ivory, are of various sizes and patterns, some with sharpened edges, to be used as a lancet for scarification. The quills are cut from goose-feathers, in pieces of an inch or more, the virus being collected on the convex surface. They have the economical advantage of subdivision.

Period of Activity.—It is the custom of most virus propagators to limit the warrant of efficiency to twenty days or three weeks, and considering the vicissitudes of weather, temperature, dampness, etc., to which it is liable in transit, this limit is sufficiently long, though it may become inert in a shorter time, and also may be found active after six weeks or more. In one case a whole year is reported.

Frauds.—From my own observation and that of others, it appears that certain modes of dilution and substitution have been practised in the use of vaccine lymph in this form.

The substitution of simple blood-serum for vaccine lymph. This has been alleged, and if so, I know of no possible mode of detection except by the test of use. As a substance for dilution there could be no possible motive for its use, except that of increasing the quantity of apparent lymph. The microscope could hardly be relied upon as a detective in this case.

Egg-albumen.—During the past winter the medical journals of this country have occasionally contained statements referring to the use of egg-albumen to a greater or less extent in the preparation of animal virus, and specimens of points have been shown me purporting to be prepared in this manner. One propagator has admitted their use, and defended it for certain reasons, namely: "That the ivory or bone point is somewhat porous, and hence requires a coating of albumen to prevent the vaccine lymph from being absorbed by the material of the point. Another, that the albumen is applied over the vaccine lymph as a protective agent to render it more durable. Without the least intention to impute the design of fraud to this special use of a foreign substance, I still believe it to be highly objectionable. My own experience shows that the practice is unnecessary for either of the reasons alleged. Pure vacine lymph will retain its activity sufficiently long without such protection, and, if any lymph is absorbed by ivory or bone, there is certainly a sufficient quantity left upon the surface for practical use.

Again, the addition of such foreign substances would greatly deceive the purchaser, who would naturally suppose the liberal coating to be pure vacine lymph, instead of a dilute solution of the same in egg-albumen.

Mucilage.—In 1872 a package of quills was brought to my notice, which were very small and pointed, and had upon the pointed ends a very thick coating of a substance which was almost insoluble in cold water, of brittle fracture, and totally inert for vaccination purposes. It had every appearance of mucilage of some sort of gum, and could not have been genuine vaccine lymph. I do not think that adulteration from this source would be difficult of detection, in consequence of the comparative insolubility of the gum.

Crusts.—This form of using virus is open to certain grave objections, to which the points and quills are not liable. The points are charged at a period when the lymph is clear and transparent, and free from pus or any foreign material, while the crusts are not removed for use until several days later. These few days are sufficient for the development of pus, which may often be noticed adhering to the under-surface of crusts as they are detached. In addition to the pus, various foreign substances are liable to become incorporated with the crust during the period of its formation.

In a fresh, normal crust, which I removed from a healthy cow September 29th, I detected the following elements or substances:

First, epithelium in abundance; second, lymph corpuscles; third, pus globules; fourth, fat globules; fifth, hairs; sixth, connective tissue; seventh, starch granules; eighth, fragments of organic material (dust of stable, etc.).

We find, therefore, a variety of elements entering into the composition of a vaccine crust which are extraneous to it, and all of them foreign to the special purpose of vaccination. Some of the constituents which have been proved, must naturally be liable to interfere with the action of the virus, and be productive of serious results. This statement is confirmed by the experience of several observers.

Dr. Wheeler, of Chelsea, Mass., reported a death from vaccination with a crust, and had also seen other cases of trouble following their use. He thinks vaccination with the crust more dangerous than with lymph.

Dr. Ayer, of Boston, reported that all the cases of trouble from vaccination which he had ever seen followed the use of crusts.

The late Dr. Comstock, of Middleboro, Mass., in a private letter to me in 1872, also related several cases of serious illness following vaccination with crusts.

I need scarcely refer to the use of crusts preserved in an aqueous solution. The very suggestion is revolting to any one who has the slightest knowledge of the laws of decomposition; and yet instances are on record of the use of such solutions, with disastrous results ensuing.

From the various records of analyses of crusts made by others, and also from my own examinations of their intimate structures, also from the results which occasionally follow their use, I have recently arrived at the conclusion that the use of vaccine crusts, and also all compounds manufactured from them—powders, solutions, etc.—should be abandoned *in toto*, and the use of vaccine lymph limited to that which is collected at the period of maturity of the vesicle, and dried immediately for use.

Capillary Tubes.—These are fine glass tubes, into which vaccine lymph is first drawn by capillary attraction, and the tubes are then sealed air-tight at each end. Glycerine is occasionally used for diluting the lymph, in varying proportions. Capillary tubes are used more generally in foreign countries than in the United States.

This form of using vaccine lymph is open to the grave objection, which is common to most organic fluids, of putrefactive change. Bacteria may be found in the lymph contained in carefully sealed capillary tubes in a very few hours after they are filled. Glycerine may possibly delay the change for a longer time, but will not prevent ultimate decomposition. In order to sterilize such a fluid by means of heat, it would be necessary to heat the fluid to such a degree as would also be fatal to the efficiency of the virus. The only safe mode of avoiding decomposition would be to collect the lymph under antiseptic spray, immediately after the puncture of the vesicle.

One writer, in advocating the use of capillary tubes, prefers them because "the lymph is always in a fresh state." If by fresh he means free from organic change, the microscope certainly does not confirm the statement.

In conclusion, I would urge the necessity of the highest standard of purity in the preparation of an article of such vital importance to the health of the republic, not only that the objections of the opponents of vaccination may be forever silenced, but also that the possibility of unfortunate results may be prevented, and the perfection of purity and excellence insured.

The discussion of this paper was made the special order for the afternoon session.

Afternoon Session.

Dr. A. N. Bell, of Garden City, L. I., read a paper on *Sanitary Inspection.*

Dr. Bela Cogshall, of Flint, Mich., read a paper,

IS TUBERCULAR CONSUMPTION A CONTAGIOUS AND PARASITIC DISEASE?

Taking the ground that it is so communicable. He related many interesting experiments to show that cattle affected with consumption communicated the disease to the human race by the eating of their meat and drinking their milk.

The recent investigations of Prof. Bollinger, of the University of Munich, on the artificial production of tuberculosis as induced by the consumption of diseased milk, are of the greatest importance. He claims that the milk of such animals has a preëminently contagious influence, and reproduces the disease in other animals experimented on from that point of view.

Then if it be that consumption is a contagious disease, it behooves us as sanitarians to see that the great source of infection—the sputum of phthisical patients—is done away with by its immediate destruction; thus preventing the germs being wafted with the air promiscuously about, endangering the health and lives of nurses and attendants. We should see to it that meat and milk infected with these parasites are not allowed to be eaten or become articles of commerce. He also discussed the question of its being a "parasitic disease," and related the wonderful discovery of Dr. Koch, of Berlin, who claims to have found the germ of the disease.

A paper on

COMBINED SEWERS DANGEROUS TO PUBLIC HEALTH,

by Dr. J. W. Compton, of Evansville, was read by Dr. E. M. Hunt. He urges entire abolition of the combined sewers for storm water and the ordinary domestic sewage. The present system produces, he claims, foul air chambers, where bacteria are generated and typhoid fever bred. Very small sewers will answer for the carrying off of the actual foul sewage from houses.

The Association then passed to the special order—the discussion of the question of

VACCINATION.

Dr. Foster, of Augusta, Ga., thought it unfortunate that bovine virus was the fashion at this time. He declared in favor of humanized vaccine virus. He has never been able to obtain over 60 per cent. of successful vaccinations from bovine virus. Bovine virus is unreliable. Often it fails to take, when humanized virus will do so. He thought bovine virus vaccination had its uses where there was a wholesale demand for vaccination. The long delay of bovine virus in developing itself is one of the objections to its use. He had never seen a case of vaccine syphilis.

Dr. Devron had found the bovine virus very reliable. He had successfully vaccinated the babe at the breast of the mother having smallpox.

Dr. Beckwith had used both kinds of virus. He had had indolent ulcers and gangrenous sores developed from bovine virus. The demand last fall had been so great that the producers had overworked their animals. As high as 15,000 patients had been vaccinated from one cow. He advocated a law that would make the propagators responsible for the quality of virus sent out, and suggested that it might be necessary for the government to take charge of the production of vaccine virus, as in Belgium.

Dr. E. L. Griffin, ex-president of the Wisconsin State Board of Health, said there was some conscience among propagators, some honesty of purpose. He said cases of spontaneous cowpox were rare, but cases of spurious cowpox were common. He would deprecate the vaccination of cows over four years old. He believed both kinds of virus had their use. Animal vaccine must be accepted as a great boon to humanity. The question before us is to guard its propagation. Last winter the demand for vaccine matter was enormous. Every man fell into error. Virus was sent out that ought not to have been sent. Animal vaccine is just as good now as it was a century ago. Its propagation should be entrusted to skilled labor only, and this should of a necessity be enforced by law. He thought the per cent. of success from bovine virus would compare favorably with that of arm to arm. He expected from 90 to 95 per cent. of success from proper bovine virus. Want of skill in the physicians who use the points is a potent source of failure.

Dr. Hills, of Keokuk, Iowa, had found in public trials that there was 25 per cent. of failure with humanized virus and less than 10 per cent. with bovine virus. He had never heard of smallpox "wearing itself out."

The continuation of the discussion was adjourned until the next day.

EVENING SESSION.

DR. J. L. CABELL, of Virginia, President of the National Board of Health, presented the following report from that body.

The National Board of Health having been placed by the recent action of Congress in the anomalous and embarrassing position of a body charged with important and responsible duties, and yet deprived of the means of efficiently executing them, some of its members who had been appointed from civil life felt that it was incumbent upon them to consider what course of action on their part would best subserve the interests of the public health, placed in jeopardy, as they conceive, by recent legislation. In consideration of the fact that the Board of Health owes its existence to the efforts of this Association, and of the further fact that their own appointments were largely due to the recommendations of a committee of this body, they have decided to refer the question to the Association itself, and to this end have directed me to address a communication, as its presiding officer, setting forth a summary statement of the operation of the Board since its organization in 1879, which they desire to be placed on permanent record.

The occasion is specially adapted to a review of the work of the National Board by this Association, in view of the fact that the law under which the board has accomplished its greatest and most beneficent work—that of preventing the introduction and spread of infectious diseases—will lapse by limitation unless renewed at the next session of Congress. It is for the American Public Health Association to determine how far the National Board of Health has fulfilled its mission, and whether it is to be destroyed or supplanted by adverse legislation.

Dr. Cabell then proceeded to give a summary statement of the operations of the National Board of Health from the date of organization to the present time, consisting (1) of aid to State and local boards of health in the execution and enforcement of their rules and regulations to prevent the introduction of contagious or infectious diseases into the United States from foreign countries. (2) Aid to the same parties in maintaining sanitary inspection on the Mississippi River. (3) The inspection of immigrants with reference to the protection of the people of the United States from the introduction of smallpox by said immigrants. In connection with the above branch of the operation, Dr. Cabell cited the following passage from a report made to the Senate of the United States at the late session of Congress, from the select committee to investigate and report the best means of preventing the introduction and spread of epidemic diseases. In this report the following statements are made with the unanimous approval of the committee:

"The epidemic of 1879 at Memphis and New Orleans made its appearance before the National Board had been able to perfect its plans of prevention; though it is, in the opinion of the committee, doubtful whether that epidemic could have been prevented, as it is not certain whether it originated from germs of the epidemic of 1878 which had survived, or in fresh importation of the disease. But, under the rules and regulations adopted by the Board to deal with it, it was actually stamped out in New Orleans, and confined to the limits of Memphis; and, instead of the general demoralization and panic, with suspension of business, trade, and commerce, which pervaded the country in 1878, commerce and communication with the infected cities were regulated, not stopped, or even retarded to any considerable extent, and the general business of the country went on in its usual methods, and through its usual channels, without serious interruption. Instead of panic and alarm, confidence and a sense of security pervaded the country. The great transportation companies of the South, both river and rail, are unanimous in their approval of the action and methods of the National Board in dealing with such cases, because experience has shown that they give the necessary security against the spread of disease, without stopping, or retarding to any considerable extent, commercial intercourse. They have learned from their own experience that the certificate of the National Board of Health as to the sanitary condition of any city, or place, is accepted by other cities and States as testimony coming from a strictly impartial and well-informed authority, independent of all local interests or influences, commercial or otherwise. In the opinion of the committee, it has accomplished much, and is capable of accomplishing highly important results of great benefit to the country, results which can be accomplished by no other agency."

Dr. Cabell then gave a brief account of the proceedings of the International Sanitary Conference of Washington, and expressed his regret that although the delegates of the United States obtained most important concessions of international comity, the ratification of which would have been of the utmost consequence, Congress had not yet taken the first step to secure such ratification. Dr. Cabell also gave an enumeration of the various special scientific investigations which had been conducted under the auspices of the National Board, and cited the testimony of eminent authorities of Europe to show the value of such investigations with reference to their sanitary applications. After noticing certain charges made against the board, Dr. Cabell concluded as follows:

It will thus be seen that the national health organization, which the Association has been so largely instrumental in bringing into existence, is in some danger of extinction for the want of adequate support by the National Legislature. In view of this fact it is considered pertinent and proper to suggest that the members of this Association may do a most useful work in instructing their representatives in Congress as to the value of the work performed by the National Board of Health, and the indisputable necessity of more liberal appropriations to enable it to carry on this work with due efficiency. Without such effort there is danger of losing the ground gained in 1879, which if so lost now will probably not be regained for many years to come. In making these efforts it may be important to bear in mind the source and character of the hostile agencies combined to overthrow the National Board of Health. We may be permitted to refer to a few of them:

"1. The State Board of Health of Louisiana, backed by a portion of the press of New Orleans, in its repeated allegations that the National Board of Health has interfered with and obstructed the local authorities, instead of aiding them, as required by law. The interference consists in the National Board establishing an inspection service within the limits of New Orleans, being induced to take this action in compliance with the request of the health authorities of the Mississippi valley States, including those of Louisiana itself. Nothing short of this will satisfy other communities having intercourse with that city, which would certainly be quarantined by its neighbors to a most inconvenient extent if it were not for the protection it derives from the certificates of the inspecting agents of the National Board.

"2. The powerful influence of the Treasury Department, which asserts a claim to the disbursement of all funds appropriated by Congress for the suppression of epidemics, and to the selection of its own medical officer, the chief of the Marine-Hospital Service, as its

agent in these operations, although an express provision of an existing Act of Congress repeals all previous acts conferring sanitary powers on that branch of the public service, and clothes the National Board of Health, which includes in its membership a detailed officer of that service, with all the power assumed by the general government in respect to quarantine and sanitary matters.

"3. As composed of medical men selected without regard to party affiliations, and wielding no political patronage, the Board finds no hearty support from politicians of either of the great parties of the country.

"In conclusion, we desire to say that, as the present membership of the Board was largely due to the unsolicited choice of the advisory committee of the Public Health Association, we abide its decision as to our longer continuance in these positions, preferring, if deemed consistent with the public good, to be relieved by the selection of others, who may, perhaps, command a larger share of public support.

"S. M. Bemiss,
"R. W. Mitchell,
"T. L. Verdi,
"J. L. Cabell,
"Stephen Smith,
"H. A. Johnson."

On motion of Dr. Early, of Kentucky, a vote of thanks was extended Dr. Cabell for the paper just read.

The Secretary then presented the following resolutions, which had been prepared by the Executive Committee in view of Dr. Cabell's report, referred to the Advisory Council, and again referred back to the Executive Committee for revision:

THE ASSOCIATION'S RESOLUTIONS.

"*Resolved*, That this Association has listened with great interest and satisfaction to the analysis and detail of the work accomplished by the National Board of Health, as furnished by the President of the Board; and that we commend its careful perusal to all upon whom, as legislators or sanitarians, devolves the care of the public health, not only as showing the scope of its faithful and efficient administration, but as suggesting and illustrating the permanent demand there is for a sustained national organization of this general character.

"*Resolved*, That there is a work to be done by such a board which cannot be done by any local or State board, and which is not, and cannot be, adequately represented or fulfilled by any other branch of the national service, as illustrated in its inspections and inquiries into special conditions so serious as to be national rather than local; in its dealings with yellow fever and smallpox; in its plans for consular health bills from foreign ports and refuge stations for a wide coast range; in its internal care over river and railroad transportation; in its investigations into malaria and other widespread causes of disease; in its valuable scientific and practical inquiries into the causes and courses of epidemics; in its comparisons of statistical facts, and in its widespread distribution of information most intimately affecting the vital conditions of our whole population.

"*Resolved*, That, while each State and each division of national service may contribute much aid in their respective spheres, we view with regret any curtailment of the functions of a board so constituted as to represent and unify the health interests of the entire Nation.

"*Resolved*, That, we counsel the National Board to continue all the work possible under its present restricted appropriations and await with confidence the extension of its powers of usefulness, and that appreciation of its work for the past and its necessity for the future, which can but result from a calm and careful estimate of the safeguards requisite for national health and prosperity.

"*Resolved*, That the Advisory Council of this Association, representing, as it does, the sanitarians of the various States, be directed to use all laudable efforts to place before the President of the United States and Congress at Washington, and before members of Congress in their several States, the very great importance to the welfare of this country of such action by the United States government as shall increase, to the fullest extent, the means and powers of usefulness of the National Board of Health.

"*Resolved*, That so long as the United States government confines its maritime and inland quarantine service to the aiding of State and local boards of health, it is essential, for the best results, that such aid shall be through channels most generally acceptable to State and local boards of health, whose co-operation is requisite; and we sincerely believe that the National Board of Health, is the channel most generally acceptable.

"*Resolved*, That confining the work of the board to cholera, yellow fever, and smallpox is believed to be in the highest degree injudicious. It should have the full powers for investigation of all preventable diseases conferred upon it by its constituting Act, and be granted the funds necessary for this purpose, and this should be done irrespective of the action which may be taken with regard to quarantine.

"*Resolved*, That the members of the American Public Health Association hereby pledge their individual co-operation in endeavoring to secure such national legislation as shall insure to the National Board of Health such material aid as may be needed in carrying out, with the greatest efficiency, all measures pertaining to the interests of public health.

"*Resolved*, That the president, vice-presidents, and secretary of this Association be charged with the duty of securing the complete presentation to the authorities at Washington of the full influence of this Association in favor of properly and permanently sustaining the National Board of Health.

"*Resolved*, That the address of the President of the National Board of Health, together with these resolutions, and such other papers or resolutions as relate to this subject, be printed at once in pamphlet form, to the number of one thousand."

Dr. Early thought no physician could fail to realize the importance of the situation. He was indignant that a government like ours should say to the American people: "We have so little regard for your health that we propose to take from you every safeguard which the National Board of Health has hitherto devised." He offered an additional resolution, strongly indorsing the action of that Board and denouncing the opposition thereto, which was favorably reported by the Executive Committee.

Dr. Devron, of New Orleans, a member of the Citizens' Auxiliary Association of that city, said his association would see with fear the abolition of the National Board.

Mr. Colter, of Chicago, mentioned the probability of our having cholera in the country within the next few months. What could be done in that case without the National Board of Health? The National Board works in unison with the State boards, and without it there could be no unity of purpose among them. Every member should work for this Board as an individual.

Dr. Cantwell, of Alabama, said the entire sentiment of his State would support these resolutions.

Dr. Thornton, of Memphis, said his city had been one of the greatest beneficiaries of the National Board. No other body could inspire the same confidence as

has the National Board. The commerce of the river will be most seriously interfered with next summer if there is danger south of Memphis.

DR. HILLIS, of Iowa, heartily indorsed the sentiments of the resolutions, but he did not think the way to reach Congress was by denunciation. Most congressmen are in favor of sustaining the National Board of Health. Some of the congressmen of the last Congress had axes to grind.

DR. BAILHACHE, of the Marine-Hospital Service, and also a member of the National Board of Health, said the officers of the first-mentioned organization were quite as competent to take charge of quarantine regulations as the officers of the National Board. There has been no legislation interfering with the constituting Act of the National Board. The quarantine act will expire by limitation soon.

COLONEL HATTON, of Tennessee, reiterated the statements of Dr. Thornton of the deep obligation of Memphis to the National Board. Perhaps the Marine-Hospital Service might do the same work, but the National Board has been tried and found effective; it has all the machinery; why make any change? We don't want the shotgun quarantine, but the only way to prevent it is by the strong arm of the National Government. The commerce of this country on the Mississippi is carried on by confidence. One day's stoppage of the commerce of this river would cost the country millions. Memphis will protect herself if the nation don't protect her.

DR. HUNT, of New Jersey, spoke of the heartfelt experiences given him by people from the South in regard to the efficacy of the National Board.

DR. RYAN, of Texas, spoke feelingly in opposition to the shotgun quarantine system.

DR. SIMMONS, of Charleston, S. C., bore testimony to the efficacy of the National Board on the South Atlantic coast.

DR. WHITE thought it certain that the sanitarians of the country, those who know best, approve of the National Board. It is equally certain that those who have attacked that Board know nothing of its real work and efficiency. Three hundred thousand people of this country are dying every year of preventable diseases. This Board is investigating the causes of such diseases, and its work must go on.

DR. DURGAN, of Arkansas, said four years' experience with the National Board had served to give his people great confidence in it.

There was entire unanimity of feeling in regard to the support to be given to the National Board, the speeches being of the most earnest and emphatic character, and the applause being frequent and heartfelt.

The resolutions finally passed unanimously.

OCTOBER 19TH—THIRD DAY.

A resolution was passed that the Advisory Council be instructed to consider the advisability of

AN INTERNATIONAL SANITARY EXHIBITION,

At Washington, or such other city as may be thought proper, and to report at the next meeting.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President—DR. EZRA M. HUNT, of New Jersey.

First Vice-President—DR. ALBERT L. GIHON, U.S.N.

Second Vice-President—DR. J. E. REEVES, of Wheeling, W. Va.

Treasurer—DR. J. B. LINDSLEY, of Nashville, Tennessee.

Executive Committee—DR. THOMAS L. NEAL, Ohio; T. J. TURNER, U. S. N.; DR. G. P. CONN, New Hampshire; J. S. BILLINGS, U.S.A.; J. J. SPEED, Louisville; H. D. FRASER, South Carolina.

It was decided to hold the next annual session at Detroit.

DR. GIHON, U. S. N., chairman of the

COMMITTEE ON VENEREAL DISEASES,

submitted an elaborate majority report, signed by eight of the nine members of the Committee. It discusses the question in the most careful and elaborate manner, stating that there are about 2,000,000 cases of venereal diseases in the United States. It concludes by recommending an act intended to prevent the spread of contagious and infectious diseases.

REV. FRED. H. WINES, of Springfield, Ill., presented a minority report opposing legislation, fearing it would tend to the registration of prostitutes.

DR. BELL indorsed the majority report.

DR. HUNT deprecated the Association's indorsing the proposed act, although he thought it desirable that the subject should be considered by sanitarians.

On motion of DR. BILLINGS, the whole subject was laid on the table—33 to 22.

DR. GIHON earnestly protested against this disposition of the matter.

DR. ELISHA HARRIS, of New York, read the report of the

COMMITTEE ON VITAL STATISTICS,

which included the following resolution:

"*Resolved*, That the American Public Health Association recommends that the chief officer and expert adviser in the registry of vital statistics in the respective States, the three departments of the Federal Government, and the National Board of Health shall meet in conference at a convenient place during the ensuing six months, to examine and consider the outlines of laws, plans, and methods of securing the most complete and correct registration and public use of vital statistics in the several States throughout the Nation and in all branches of the public service." Adopted.

DR. O. W. WIGHT, health officer of Detroit, read a paper on *The Law Requiring Medical Men to Report Cases of Infectious Disease and Deaths to the Authorities*.

AFTERNOON SESSION.

THE REPORT OF THE TREASURER,

DR. J. BERRIEN LINDSLEY, showed total receipts of $2838.67, including a balance of $812.67 brought forward; disbursements aggregating $563.84, leaving cash on hand, $2274.63. Volume 7 of Public Health Reports is still in the hands of the printer. When it is issued and all liabilities met there will be a net balance of $300. Referred to the auditing committee.

DR. J. J. SPEED, of Kentucky, read a paper on *The Relation of Health Associations to the Practice of Medicine*.

DR. G. B. THORNTON, President of the Board of Health of Memphis, read a long and elaborate paper on

THE NEGRO MORTALITY IN MEMPHIS,

in which he considered the sanitary and social conditions of the colored race. He reviewed at length the relative vital movements of the two races.

DR. JAS. F. HIBBERD, of Richmond, read a paper on *Propositions Concerning Vaccination*.

DR. A. W. CANTWELL, of the Board of Health of Davenport, Iowa, read a detailed history of *An Epidemic of Smallpox by Direct Importation from Germany on the Steamer Candia*.

A paper by JOHN W. DETWILER, of Bethlehem, Pa., on *Smallpox in Bethlehem and Suburbs*, was read by title.

The subject of

VACCINATION

was now taken up for general discussion.

Dr. Hunt said there is such a thing as protected humanized virus, and there is also such a thing as protected bovine virus. The sources of trouble in vaccination are: Virus produced by unskilled propagators; virus improperly inserted; virus which has lost its strength by age; persons in bad health when vaccinated.

Dr. Dawson deprecated the inoculation of the cow with smallpox and the use of the virus thence produced as a preventive of smallpox.

Dr. Hillis dissented from the views of Dr. Hibberd on public vaccination. In his community public vaccination had been completely enforced. He thought Dr. Hibberd had given his people too much time to work up an opposition to vaccination. The attempt to enforce vaccination where there is no smallpox is liable to be attended with difficulty. In his town, the schools, places of amusement, churches, etc., had been closed, and only the briefest notice given of the intention to vaccinate.

Dr. Beckwith defended Dr. Hibberd. Unless the vaccine virus can be guaranteed pure, there can be no justification for compulsory vaccination. He stated a number of cases where ulcers, etc., had resulted, and one case where consumption had followed.

Dr. Griffin thought there was little likelihood of the cow being inoculated with smallpox. It had amused and surprised him that so many medical gentlemen were of the opinion that the lymph was derived from cows inoculated from smallpox patients. In regard to the variolation of the cow, he said most of those who have attempted it have come to grief.

Dr. Wright thought it possible, though extremely difficult, to convey human smallpox to the cow, and to reconvey it again to the human subject. He thought real vaccinia in the cow identical with smallpox in the human subject. There is no such thing as the substitution of one zymotic disease for another. So far as the State enforces vaccination, just so far is it bound to see the virus is pure. No man should be allowed to sell vaccine matter who is not responsible to the State. He paid a high tribute to Dr. Griffin's vaccine matter. He thought the time was not ripe for enforced vaccination. He absolutely knew vaccination was a protection against smallpox. He had vaccinated eleven persons in a pest-house, not one of whom had taken smallpox.

Dr. Bailey, of Louisville, thought we should rely upon moral suasion in educating the people up to vaccination. He had not much apprehension of the transmission of diseases by vaccination.

Dr. Raymond, of Brooklyn, protested against spasmodic vaccination. Where vaccinators are kept constantly on duty, they are known and no prejudice is occasioned. Compulsory vaccination would never be heard of because it would never be needed if regular vaccinators were employed all the time. He thought local records should be kept of smallpox cases and vaccination, as of much better moral effect than the testimony of foreign experts on the efficacy of vaccination.

Dr. Abbott, who read the first paper calling out the discussion, thought there was reason to believe in cases of spontaneous cowpox. It is most difficult to communicate from such animals the genuine bovine disease to other animals.

Dr. Herrick, of New Orleans, suggested that the disease was communicated to the cattle through the human beings by whom they were milked.

Dr. Durgan, of Boston, believed in persuasion, but he also believed in a law which compels wholesome sanitary observances. Isolation and vaccination are two means by which we suppress a smallpox epidemic. Compulsory vaccination works well in Massachusetts and admirably in Boston. We use only animal virus on ivory points. The humanized virus is a little more certain to take on the first trial.

After the reading of several other papers and the passage of the usual resolutions of thanks, the Association adjourned.

NEWS ITEMS.

INDIANAPOLIS.

(From our Special Correspondent.)

The Meeting of the American Public Health Association.—The session of the American Public Health Association in this city, which has just closed, has been, upon the whole, a fairly interesting and successful one. The number of members registered is about one hundred and forty, an attendance not so great as that at some previous meetings, but still exceedingly good when the peculiar circumstances of this meeting are considered. The local committee of management was so constituted as to cause great distrust on the part of all respectable physicians, its chairman being a homœopathic physician who does not command the respect of his own fraternity, and who is commonly known among them, as he is among the citizens of Indianapolis, by his initials (M. T.) "Empty Runnels." When about a dozen of the older members of the Society, including the executive committee, arrived here on Monday, they were met by the report that this Runnels had made arrangements to bring in about one hundred and fifty homœopathic and physio-medical friends and take possession of the Association. He had prepared for the press a programme for the first evening, on which he had placed his own name as presiding officer, and seemed bent on making his unpleasant personality as conspicuous as possible. The local medical society had, by formal resolution, advised the regular physicians of the State to have nothing to do with the matter, and, at first sight, it seemed as if the best thing that a respectable medical man could do would be to keep aloof and out of the controversy which seemed to be impending.

The importance of the objects of the Association was, however, felt to be so great, and the destruction of its influence for good if it passed under sectarian control was so certain, that it was clear that the first duty of the members present was to endeavor to thwart, if possible, any movement to control the Society by local influences. To this end the Executive Committee refused to admit any new members until action should be taken on a Constitutional Amendment, which provided for the division of members into two classes—those having and those not having the right to vote. Accordingly, the first business of the first day's session was to pass this amendment after a rather warm discussion, in which Dr. Hewitt, of Minnesota, and Dr. A. N. Bell, of Brooklyn, combined with Drs. Verdi, Runnels, and others in the attempt to break down the barrier and allow every and any one to become a member by paying five dollars.

At first this action was looked upon with great distrust and irritation by the homœopaths—who thought they were going to be entirely excluded, but when they found that the Executive Committee was electing homœopaths and approving the reading of papers prepared by them, and was simply judging of their qualifications from the standpoint of sanitarians, the excitement cooled down, and by this time some of the leaders in the opposition were quite satisfied with the result.

The second point upon which it seemed as if there

might be some serious differences of opinion was with regard to the National Board of Health. Dr. Hewitt, the Secretary of the State Board of Health of Minnesota, tried hard for two or three days to organize an opposition to any action in favor of the National Board, and was always to be seen in confidential talk with one or another member urging his view. He does not represent the views of his Board which is decidedly friendly to the National Board, and it is a little difficult to get at the cause of his persistent hostility.

The only explanation to be obtained was from a big northwestern member, who when questioned on the matter said, "Well you see Hewitt is what we call a sorehead. He is very smart, thinks very highly of himself, and generally is down on anything that he can't control. He wasn't consulted about the Board, he can't run it, and he is a little afraid of it."

When the subject of the National Board and its present anomalous position came before the Association on Wednesday evening, in the form of a long report from Dr. Cabell, President of the Board, it was very soon apparent that the sentiment of the meeting was almost unanimous in favor of the support of one national sanitary organization, and moreover, that this feeling was a very strong and earnest one. Speaker after speaker representing all parts of the country denounced in strong terms the action of Congress in limiting the scope of the work of, and refusing funds to the National Board, The only dissenting voice came from the representative of the Marine-Hospital Service, who claimed that that service could do the quarantine work better than the National Board, and ought to have it. In this opinion he seemed to be quite alone, the general expression of opinion indicated a decided want of confidence in the Marine-Hospital Service. After the meeting was over a prominent member of the American Medical Association asked me how far the Code of Ethics was applicable to a medical department represented in that body, and whether, when such a department persistently and systematically sought to break down and destroy another medical department simply to get possession of funds and patronage, it was not clearly a violation of the Code? I propound his queries for your consideration.

The event of Thursday morning was the report of the committee on venereal disease by Dr. Gihon, of the Navy, and the laying it on the table by the motion of Dr. Billings, of the Army. This result, which seems to have been totally unexpected by the committee, was by no means satisfactory to it, and Dr. Billings was accused of having taken an unfair advantage of parliamentary tactics to suppress debate and permit of no reply to his own rather sarcastic speech on the subject. Dr. Billings reply to this, as I heard him give it to one of the aggrieved committee-men, was that he had specially tried to have the fullest possible discussion, and had requested the President to recognize him only after all who desired to speak had had the opportunity—telling him what he proposed to do which would of course stop all further debate.

Dr. Billings said he was so sure of the folly of bringing the Association into conflict with the medical profession of the country, by approving a law which would practically make it compulsory upon physicians to reveal the secrets of their patients, and also for the reasons given by him in his remarks, that he certainly meant to kill the measure if possible—but that he had to make the motion when he did or not make it at all.

In this connection I must allude to the very ludicrous termination of the movement for an international sanitary exhibition. Circulars, calling a conference of State boards of health with the National Board and the American Public Health Association, and purporting to be signed by a number of well-known sanitarians, and by Dr. Newell of New Jersey, as secretary of a conference of sanitarians held in New Jersey, in September last, had been sent to all the above-mentioned organizations, asking them to send delegates to a conference to be held at Indianapolis, to organize the proposed exhibition. A number of delegates were present and the meeting took place in the reading-room of the Grand Hotel. Dr. Newell took the chair and announced that the objects were to select a name for the organization, to determine where the exhibition should be held, what it should contain, etc. After a moment's silence, one delegate mildly suggested that it would be as well to decide first whether there should be any exhibition at all. Whereupon, Dr. Billings took the floor and showed that the conference of sanitarians of which Dr. Newell claimed to be secretary, consisted of four gentlemen whose names were quite unknown to the Secretary of the State Board of Health of New Jersey, that permission to use the names of the supposed signers of the call had been obtained under a species of false pretences, and that the Public Health Association repudiated any connection with the movement. He concluded by advising those present to have nothing to do with the matter and bowed himself out of the room, whereupon all present got up and followed him leaving Dr. Newell in the chair, alone in his glory.

Your correspondent was present as a sort of self-constituted delegate, and anything more ludicrous than the expression of mingled surprise, humiliation, and wrath, on the face of the would-be promoter, as he saw the procession file past him, I have never had the good fortune to see. One delegate, upon reaching the hall, christened Dr. Billings as "the sanitary refrigerator," amid shouts of laughter.

The complications arising from the unfortunate composition of the local Committee of Arrangements resulted in an almost total want of the social element, so far as the residents of the city were concerned. There were no receptions or entertainments, and very few of the local physicians attended the meetings. I am by no means sure, however, that this was not all the better for the objects of the society.

The selection of the officers for the next year seems to have given very general satisfaction, and the prevailing opinion is that the meeting next year at Detroit will be a great success.

Progress of the Yellow Fever.—The despatches from Pensacola, Florida, are incomplete this week, as no bulletin was telegraphed on the 22d. On the other days the record was as follows:

Dates.	Cases.	Deaths.
October 17th,	50	3
" 18th,	56	3
" 19th,	53	9
" 20th,	42	2
" 21st,	40	3
" 22d,	—	—
" 23d,	37	1
	278	21
To October 16th,	1680	143
Total reported to date,	1958	164

The new cases reported during the week ending 16th inst. were 380. The disease is thus apparently decreasing.

The investigation into the origin of the epidemic has been turned over to Dr. Wm. Martin, of the U. S. Navy. Major Walthall, of Mobile, who was originally suggested for this work, was prevented from undertaking it by the pressure of his present duties in con-

nection with the sick of the fever-stricken city. Dr. Jerome Cochrane, of Alabama, in a letter to Major Walthall, makes the following suggestions as to the lines of inquiry:

"The history of every infected vessel that has been in the bay of Pensacola this summer should be carefully studied in all its possible antecedents and consequences—the history of the Saleta, the Accame, the Iris, the Rosa B——, the —— McNeil, the Duc Amici Luigi, and all the rest.

"The Saleta and the Accame should be specially studied. I am sure that they got their infection either at the quarantine station or in the city itself; and I am very much of the opinion that a thorough study of the cases of these two vessels will solve the problem of the introduction of the fever. One notable fact in connection with all of these infected vessels is the fact that the officers were the first to have the fever; the officers —that is to say, the men—whose freedom of movement was least restricted, and who were most frequently at the supply house, and most frequently ashore.

"The first cases on shore did not occur along the shore of the Bay, near the wharves, as might have been expected on the hypothesis that the fever was brought from the shipping, and almost a whole month passed away after the presence of the fever in the city was recognized before any stevedore, or any person accustomed to work on the ships, or any of the women in the lewd houses frequented by sailors, was attacked by it. It would seem to follow that the fever was brought in, not by the common sailors, but by the officers. Still, no case has been traced to any connection with the Saleta; and no subsequent case has occurred at Mrs. O'Neal's, where the captain of the Accame died, or anywhere in the neighborhood of Mrs. O'Neal's.

"There can be no doubt that the fever had really found a footing in the city many days before its dread presence became known, either to the people or to the health authorities; and the most persevering efforts should be made to discover the really "first cases." To this end the antecedents of the first cases that were recognized should be thoroughly traced out; and in this connection an investigation should be made of every case of fever that occurred anywhere in the neighborhood of the district that first became infected for two or three weeks or a month before the annunciation of the fever on the 28th of August. In this list came the cases in the Rosario family, near the jail, and several other cases that occurred in that immediate neighborhood, whose names I cannot now recall. The probabilities all point to this locality as the *fons et origo* of the epidemic, and here the research should be made in a spirit that refuses to be baffled. Spend days and weeks here, if necessary. Interrogate every human creature in the neighborhood, and note every smallest occurrence. Somewhere about here the key of the problem is to be found."

Cholera in Yokohama, Japan.—During the two weeks ending September 25th, there were in Yokohama and vicinity 101 new cases of cholera and 85 deaths from the disease. This is a very notable and encouraging decrease, the figures for the first twelve days of the month having been respectively 283 and 223. The totals since the commencement of the epidemic, on April 26th to date, are 3610 cases and 2308 deaths, giving a mortality of a little over 63 per cent. None of the foreign residents are affected at this time.

The total number of deaths from cholera in the Empire is stated, in a Yokohama paper, to have been 21,030 on September 10th.

No Cholera in Morocco.—The National Board of Health has received information through the Department of State from Mr. Mathews, United States Consul at Tangier, dated Sept. 18, that cholera is not prevailing in Morocco. "I may add, also," says Mr. Mathews, "for the benefit of American merchants and tourists, that of the telegrams from Madrid to the London papers announcing the appearance of cholera at Tangier, and that the Spanish government had adopted rigorous measures to prevent the introduction of the disease into Spain, the former part is without fundation. Neither at Tangier nor at any place in Morocco have contagious diseases broken out; if, unfortunately, such had been the case, even the least sign of disease, I could not have failed to report the facts in my weekly returns to the National Board of Health at Washington."

The Sanitary Council of the Mississippi Valley held its Annual Session at Indianapolis, on Thursday, October 18, Dr. Gustav Dervon, President, in the chair.

Dr. J. H. Rauch, of Chicago, the Secretary of the Council briefly stated the objects of the meeting.

On motion of Dr. Baker, of Michigan, a committee, consisting of one from each State represented in the Council, was appointed to formulate an expression of opinion with regard to the work of the National Board of Health and the necessity for its continuance; said committee to report at an adjourned meeting to be held at 5.30 P.M.

On motion of Dr. Thornton, of Memphis, it was decided to hold the next annnal meeting of the Council at Jackson, Miss.

The Council then adjourned to 5.30 P.M., at which hour it was again called to order by the President, and the committee appointed at the morning session, through its chairman, Dr. J. J. Speed, of Kentucky, submitted the following:

Resolved, That the Sanitary Council of the Mississippi Valley earnestly deprecates any effort to curtail the work of the National Board of Health as likely to result in a renewal of panic and unnecessary interference with commerce and travel.

"*Resolved*, That, in the judgment of this Council, founded upon intimate and extended experience, the river and rail inspections of the National Board of Health are essential to secure the confidence of the Mississippi valley and thus to prevent avoidable interruption and disturbance of business interests, and the Council, therefore, petitions Congress to give such aid to the National Board of Health as will enable it to efficiently carry out its system of sanitary inspection for the prevention of the spread not only of yellow fever and smallpox, but of all epidemic, contagious, or infectious diseases.

"*Resolved*, That this Council fully indorses the action of the American Public Health Association, as set forth in the resolutions concerning the National Board of Health, adopted at the session of the Association held October, 18, 1882, and urges each organization represented in the Council to use its utmost endeavors to influence members of Congress from their respective districts to promote the necessary legislation to secure the end above indicated.

"*Resolved*, That the Secretary of the Council be instructed to transmit a copy of these resolutions to the American Public Health Association and to each organization represented in the Council."

The resolutions were unanimously adopted, and on motion the meeting adjourned.

Opposition to Koch's Theories as to the Bacillus Tuberculosis.—Before a largely attended meeting of the Philadelphia County Medical Society, held Wednesday, October 18th, Dr. H. F. Formad

made a demonstration of the bacilli tuberculosis, and made some remarks in which he claimed that so far there had been no reliable demonstration of the etiological relation of these bacilli to phthisis. He did not dogmatically deny it, but did assert positively that it could by no means be considered as proved. He objected to the importance attached to the reaction of those bacilli to certain staining fluids, because from his own experiments he had found it not to be peculiar. The result of Koch's inoculation experiments he discredited, because the successful ones had been made only on animals that have a very strong predisposition to tuberculosis, and contract it from inoculation of non-specific substances; while others claimed to be successful, he regarded as cases of pseudo-tuberculosis.

The view, in regard to the bacilli tuberculosis to which Dr. Formad inclined was that they do not cause the disease, while it is likely that they do "condition the fatal issue."

The remarks, which will be published in full hereafter, were received with marked interest, and were followed by a brief discussion, participated in by Drs. Wood, Gross, Tyson, Bartholow, Cohen, and others. None of the speakers seemed to have adopted Koch's views, and it was spoken of as a matter for congratulation, that one so well fitted as the first speaker, should have presented the arguments against them; since the truth would be arrived at all the more surely if the new doctrine were put upon its defence and not allowed to establish itself without due scrutiny.

THE KING'S COUNTY MEDICAL SOCIETY AND THE NEW YORK CODE. — At the stated meeting of this Society held on the 17th instant, the consideration of the new Code came up as special business. Dr. E. R. Squibb presented a series of resolutions condemnatory of the Code, upon which further action was postponed until the next meeting.

RESIGNATION OF DR. OLIVER WENDELL HOLMES.—DR. HOLMES has just resigned the Parkman Professorship of Anatomy in Harvard University, to which he was elected thirty-five years ago, as successor to the late Dr. John C. Warren. It is understood that Dr. Holmes intends to devote himself entirely to literature.

THE LOWELL INSTITUTE LECTURES.—PROF. WILLIAM B. CARPENTER, the distinguished English physiologist, has just begun a course of six lectures on "The Physical Geography of the Deep Sea." They are being delivered in Boston before the Lowell Institute.

NEW YORK POLYCLINIC.—A polyclinic has been organized in New York for the purpose of giving post-graduate instruction in clinical medicine and surgery, didactic lectures being excluded from their methods of teaching. A dispensary has been opened under the direction of the faculty. There will be five sessions of six weeks each, commencing November 7th. The faculty consists of Drs. Leaming, Ripley, Hudson, Elsberg, Gray, Brandeis, Robinson, Bronson, Fowler, Wyeth, Gerster, Mundé, Wylie, Gruening, Webster, Gibney, and Stillman.

CARTWRIGHT LECTURES.—DR. W. T. BELFIELD, Lecturer on Physiology in Rush Medical College, will deliver the Cartwright Lectures this winter. He has chosen "Disease Germs" for his subject.

OBITUARY RECORD.—Died in Brooklyn, N. Y., October 12, 1882, ABRAM LELAND LOWELL, M.D., aged 50 years. He was born in Chester, Vermont, the son and the grandson of a physician, both distinguished practitioners, and was easily inducted into the study of medicine, and early manifested a fondness for surgery and anatomy. He was graduated in arts at Harvard University in 1857, and in medicine at the University of the City of New York three years later. He was an interne on the surgical side at Bellevue and Charity Hospitals in New York soon after graduation. During the war he was for a time the surgeon of the steamship Arago; a little later he occupied a very responsible position in the Pension Bureau. About 1872 he took up his residence in Brooklyn, and soon afterwards became an attending surgeon to St. Peter's Hospital, where he made a record for conservatism, skill, and self-sacrificing interest in his work that will long be held in memory by the surgical patients of that institution.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending Oct. 14, 1882, indicate that consumption, influenza, and neuralgia have increased, and that diarrhœa, pneumonia, erysipelas, and puerperal fever have decreased in area of prevalence.

Compared with the average of reports for the months of October in the preceding five years, all diseases named in this report, except smallpox, were less widely prevalent during the week ending Oct. 14, 1882, than has been usual.

Including reports by regular observers and by others, diphtheria was reported present during the week ending October 14, and since, at twenty-three places, scarlet fever at fourteen places, measles at two places, and smallpox at four places, as follows: in Orange and Ionia townships, Ionia County, October 13; at Grand Rapids, October 14; at Niles (one case), October 19.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 16 TO OCTOBER 23, 1882.

WILLIAMS, JOHN W., *Surgeon.*—To proceed to Vancouver Barracks, Wyoming Territory, and report upon arrival to the Commanding General, Department of the Columbia, for assignment to duty in that Department.—*S. O. 168, Military Division of the Pacific, October* 13, 1882.

MOORE, JOHN, *Major and Surgeon, Medical Director, Headquarters Department of the Columbia.*—Granted leave of absence for one month, with permission to apply to Headquarters Military Division of the Pacific for extension of one month.—*S. O. 145, Department of the Columbia, October* 3, 1882.

LORING, LEONARD Y., *Captain and Assistant Surgeon.*—Granted leave of absence for four months.—*S. O. 243, A. G. O., October* 18, 1882.

BYRNE, CHARLES B., *Captain and Assistant Surgeon.*—Leave of absence extended ten days.—*S. O. 243, A. G. O., October* 18, 1882.

BUSHNELL, GEO. E., *First Lieutenant and Assistant Surgeon.*—Leave of absence extended one month.—*S. O. 244, A. G. O., October* 19, 1882.

APPEL, A. H., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for one month.—*S. O. 168, Department of Dakota, October* 14, 1882.

CARTER, EDWARD C., *Assistant Surgeon.*—Now at Camp Price, to proceed to Fort Thomas and report to the Commanding Officer of that post for duty.—*S. O. 159, Department of Arizona, October* 11, 1882.

EVERTS, EDWARD, *Assistant Surgeon.*—Assigned to duty at Fort Coeur d'Alene, Indian Territory.—*S. O. 145, Department of the Columbia, October* 3, 1882.

TAYLOR, A. W., *Assistant Surgeon.*—Relieved from duty at Fort Supply, Indian Territory, and assigned to duty at Fort Cummings, New Mexico.—*S. O. 208, Department of the Missouri, October* 16, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

ARTIFICIAL FEEDING OF INFANTS.

A Clinical Lecture delivered at the Pennsylvania Hospital, October 25, 1882.

BY ARTHUR V. MEIGS, M.D.,
PHYSICIAN TO THE HOSPITAL.
(Reported by CHARLES BAUM, M.D.)

GENTLEMEN: I have here two French books, from each of which I will read you an extract as an introduction to my subject for to-day. That subject is the artificial feeding of infants, with the importance of which it will be my endeavor to impress you. These books are *La Vérité sur les Enfants Trouvé*, par le Dr. Brochard, Paris, 1876, and *Histoire des Enfants Abandonnés*, etc., par Ernest Semichon, Paris, 1880.

M. Semichon says, "In the archives of Rouen we find that between Jan. 1, 1800, and Dec. 31, 1859, inclusive, thirty-six thousand five hundred and four infants were placed in the 'Tour' of the foundling hospital. About thirty-two thousand eight hundred and fifty or sixty of these died in the sixty years, making a mean of about ninety deaths in each hundred."

My quotation from the book of Dr. Brochard is as follows: "There appeared a few months ago, in the 'petit journal,' the following: 'Nothing more original, and at the same time more practical, can be found than the new dog kennels at the Zoölogical Garden. This actual palace contains the purest and most useful types, from the terrier to the large Siberian grayhound, and from the bold dog of the Pyrenees to the Skye terrier. These interesting animals have large cages, with comfortable boxes furnished with bedding and coverings, and a *special cuisine!*' While the public is in ecstasies about the *special cuisine* for foreign dogs, there die each year in the foundling hospital at Lyons, during the first eight days after birth, one-tenth of all the infants taken there, for want of a *special cuisine;* that is, for want of wet nurses. At Tours, in the foundling institute, the mortality in 1872 was forty-one in ninety-one, thanks to the want of a *special cuisine;* that is, to the want of nurses. In 1874 the mortality at Tours was, from the same need, 86 or 87 in 100. What a pity the foundlings, in place of being in the care of the general government, were not in the hands of the authorities of the Zoölogical Garden! They would then be cared for as carefully as the little brutes, and would have, what they now lack, a *special cuisine* and be housed on hygienic principles."

Terrible as are the figures I have just read to you, the results attained in the foundling ward of the Philadelphia Almshouse are still worse. A few years since the published mortality was one hundred per cent., which means that every foundling taken there died. In justice to our Almshouse, and to foundling hospitals in general, it should be said that their mortality must always be high, as the infants they receive are from the very scum of the earth, being in many instances the offspring of prostitutes, criminals, and drunkards, and consequently often suffering from congenital syphilis and all forms of wasting infantile diseases; again, many of them are already half-dead from exposure upon doorsteps and cellar-ways before they are picked up and taken to an institution. All this, however, will not account for the excessive mortality in most of the hospitals, and particularly in our Almshouse. Many of the deaths are attributable to neglect and improper feeding; from carelessness and inattention to cleanliness about the food, and from ignorance, on the part of the persons in charge, of what constitutes proper diet for the new-born.

The child I now show you was born July 15, 1882. His mother, a French woman 35 years of age, and far advanced in pregnancy, was treated in this hospital for typhoid fever, and was discharged, cured, on June 16, 1882. During her entire attack she complained bitterly of pain in the hepatic region and was constipated, many scybala being discharged from time to time after the employment of simple enemeta. Just seventeen days afterwards she returned to the hospital suffering with agonizing pain in the region of the liver, accompanied with fever. There was a large discharge of pus and blood from the rectum twenty-four hours before death, and from a second attack of the same character she died. In the last few minutes of life the infant before you was born in an extremely cyanotic condition, respiration being only slowly and with difficulty established. His entire cutaneous surface was soon found to be jaundiced to an unusual degree; this, however, gradually disappeared.

A post-mortem examination of the body of the mother showed the gall-bladder to have been converted into an abscess, which was adherent to the small intestine, into which perforation had taken place. Five large gall-stones were found in the sac, and seven others in the intestine. There were cicatrices in many of Peyer's patches in the ileum.

The infant was very small, but its finger-nails were well formed; the facial expression was that of an old man, the forehead being wrinkled, and the skin harsh and dry. The muscles were flabby. The food ordered for it was milk one part and water three parts, with ordinary cane sugar to make it moderately sweet. Upon this it did not thrive, having much colic, and green stools with occasional vomiting of firm curds, want of appetite, and sleeplessness.

On the first of August, when I assumed charge of the ward, this infant was taking from three to four fluidounces of diluted milk in the twenty-four hours. He had frequent green stools, and his condition was so bad that all the persons in charge of him had fully determined that he must die. I at once placed him upon the use of a food I have devised within the last year, and with which I have thus far attained very good success in as many cases as I have had the opportunity to try it. It contains the same elements as are found in human milk, and in more nearly the same proportions, than any other food heretofore recommended. This consists of two parts of cream, one of milk, two of lime water, and three parts of a solution of milk sugar of the strength of 17¾ drachms to the pint of water. The milk to be used, should be good ordinary cow's milk, and not the very rich milk of Jersey or other high-bred stock, and the cream in the same way should be such as is usually sold in cities, and not too rich, containing about 16 or 17 per cent. of fat. The quantity of this food taken by a new-born infant should be two or three fluidounces every two hours, and if it thrives, it will soon take as much as a gill every two hours.

The best way to prepare and use my food is to order five or six packages of milk sugar, containing 17¾ drachms each; the contents of one of these to be dissolved in a pint of water, and each time the child is to

be fed, let there be mixed together, and then warmed, three tablespoonfuls of the sugar solution, two of lime water, two of cream, and one of milk. This makes about a gill, and as much of it as the child does not take should be thrown out, and a fresh mixture made for the next feeding. The solution of sugar should be kept in a cool place, and at once thrown away if it sours, as occurs if kept more than a day or two in warm weather. The dry sugar keeps indefinitely, and is easily dissolved in warm water. A pint bottle should be kept for the purpose of containing the solution, to serve also as a measure of the quantity of water to be used with each package dissolved, and also to save further measuring.

The infant I show you, was at the same time ordered twenty drops of brandy, to be given every two hours, and a few days later took four times daily a teaspoonful of a 25 per cent. emulsion of cod-liver oil, containing in solution a quarter of a grain of pyrophosphate of iron. Shortly after he began the use of the food and tonics his condition improved; he became much less wrinkled and had a better color; his appetite awakened and he would cry when hungry, instead of lying in a lethargic condition, as he did during the first two weeks of life. As the improvement progressed he passed a very large quantity of urine, it being impossible to keep him dry. This is a symptom I have frequently noticed in infants recovering from wasting conditions, resulting from malnutrition. His condition was one of progressive improvement until about Sept. 26, when he became feverish and had some slight coryza; a macular and scaly syphilitic eruption soon appeared upon the face, head, neck, and palms of the hands and soles of the feet. For a few days it seemed as though he would die, but under the use of mercurial ointment, of which a piece as large as a pea was rubbed into the groins once each day, and a grain of potassium iodide given three times daily, he soon improved, until he reached the condition in which I now show him to you. His daily quantity of food is now more than three pints in twenty-four hours, and he often takes more than a gill at one feeding.

About two years ago I became interested in the analysis of cow's milk, and from this I was led, by an accident almost, to attempt to analyze a specimen of human milk, My surprise was great when I found a proportion of only about one per cent. of casein instead of three to four, as exists in cow's milk. I at first supposed this to be due to some error in my process, but after making a number of analyses and getting always approximately the same result, I concluded that perhaps I had only arrived at what was actually true. In pursuing the subject I am more and more convinced of the correctness of this view. I will not here dilate further upon the actual methods of analysis, but will refer any of you who may be interested in the subject to a paper I read last winter at a meeting of the Philadelphia County Medical Society, which was published in the *Philadelphia Medical Times* of July 1, 1882.

The analyses of human milk heretofore published have differed so widely that it is impossible they can all be correct. I will quote three analyses to show you how great is the divergence of the results obtained—one by Henri and Chevallier; a second by Vernois and Becquerel, and the third by Messrs. Dolan and Wood, published in the *Practitioner* not long since.

	H. and C.	V. and B.	D. and W.
Water,	87.95	88.908	89.045
Fat,	3.55	2.666	1.764
Casein,	1.52	3.924	7.005
Sugar,	6.50	4.364	1.921
Ash,	.45	.138	.265
		100.000	100.000

You will observe that the great difference in the figures lies in the estimates of the amounts of casein and sugar, the other elements being all sufficiently nearly parallel; but I do not think it possible that human milk can vary as much as these analyses would lead us to believe; particularly the estimate of casein given by Messrs. Dolan and Wood appears to be manifestly absurd; human milk can never contain such an amount. The mean given by Vernois and Becquerel is that of eighty-nine analyses they made, and is accepted as the standard by most authorities upon the subject. An examination of the three analyses shows conclusively that if milk has any uniformity of composition at all, not more than one of the three can be correct.

In order to arrive at a correct idea of the composition of human milk I have made a number of analyses, taking upon one occasion an equal quantity of milk from twenty-seven women in the Philadelphia Almshouse, which was kindly furnished me by Dr. Fairfield, the resident physician, with the permission of Dr. John M. Keating, who had charge of the ward at the time. An analysis of this gave me an average of the composition of the milk of these women. On another occasion I procured from the same source the mixed milk of eight negro women, and analyzed it also; to these two analyses, I added eight separate analyses I had made of the milk of different women, and by a simple process of arithmetic I arrived at an average of the composition of all. This gave me the mean average composition of the milk of forty-three different women.

Taking the average thus arrived at as my standard, I have endeavored to synthetically construct a food which would be as nearly as possible like human milk in composition. Analysis of the food, the proportions of which I have already given you, show that I have at least approximated this result. I will shortly present to you the actual figures of an analysis I have made of the artificial food suggested.

No one will pretend, I think, at the present day to claim that any results have ever been attained, by any plan of artificial feeding yet devised, that are at all comparable to those obtained by nursing. In the foundling hospital of Moscow, we are told by M. Parrot that admirable results are obtained by the plan carried out there. To each two infants there is one nursing woman, either the mother of one of them or not, as the case may be; this woman is obliged to alternately nurse and feed the two infants, of whom she has charge. The success of this plan is great, but still the mortality is large. In France, as I have already shown you, the death rate is eighty or ninety per cent. and in our own city almshouse, it has been, at times at least, still worse.

Considering all this, I think it may fairly be assumed, that if we could find a food more nearly like human milk, we would greatly lesson the mortality among hand-fed infants. It cannot be that the mere drawing of the milk out of the breast through the nipple is what makes it so immeasurably the best food for the human infant. It must be that nature has prepared a food which is most digestible and exactly what is required by the infant stomach for the healthy nourishment of its body, and it is likely that if we could procure human milk as we can cow's milk, and give it to infants, we would attain a success approximating, although not equal, to that attained when the child draws its nourishment from its mother's breast.

Thus far there has been a great and unfortunate divergence in the views of physicians upon the proper method of artificial feeding. M. Parrot advises the administration of pure cow's milk; so I believe does Dr. Jacobi, of New York; many order it diluted with water, and it almost seems that the various methods are as numerous as the physicians who advise them.

Of later years, a great deal has been said about cream mixtures, and Dr. Biedert (a German) in particular has written much on the subject, strongly urging the use of diluted cream.

Condensed and preserved milks have lately attained a great reputation as admirable foods for the new-born, and the results are much better, if properly managed, than are commonly obtained by the use of simple watered cow's milk; the amount of casein in condensed milk, as ordinarily used, being less than in fresh cow's milk, and consequently the infant has not the leathery, cheesy coagula to contend with, that are so apt to be vomited when cow's milk alone is used. Preserved milk is usually ordered in this city to be given in the proportion of one teaspoonful to six tablespoonfuls of water. I made a mixture in this proportion, carefully analyzed it, and found it to contain only about one per cent. of fat; herein lies its defect as an artificial food, for this is too small a proportion of fat to adequately sustain an infant. There is rather less than one per cent. of casein, which accounts for its success, for casein so diluted cannot form leathery curds. The amount of sugar contained is also too small, being only about five per cent. The evil of giving too little fat and sugar is not such a present and active one, as the giving of too much casein, which at once forms heavy tough curds, and in all but very healthy infants soon weakens or arrests the digestion.

I will now show you in parallel columns four analyses, in order that you may inspect and compare them. It will be observed that the human milk and my artificial food are very nearly alike in composition, except in the matter of ash; while the pure cow's milk is widely different, containing a much larger proportion of casein, and less sugar. The condensed milk mixture falls below all the others in the quantity of each element, except the water and ash, and it will be observed that, as the fat and casein bear the same relative proportion to each other as they do in pure cow's milk, it would be impossible to dilute or mix it in such a way as to have the elements in the proportions contained in human milk, for by increasing the quantity of condensed milk used, to get more fat, we add at the same time too large an amount of casein.

	Human. (Mean composition from milk of 43 women.)	Artificial Food.[1]	Cow's (Wanklyn.)	Condensed. (one teaspoonful to six tablespoonfuls.)
Water,	87.163	88.357	87.551	92.673
Fat,	4.283	3.506	3.071	1.095
Casein,	1.046	1.214	4.043	.868
Sugar,	7.407	6.669	4.626	5.206
Ash,	.101	.254	.709	.158
	100.000	100.000	100.000	100.000

Theory leads us to believe that a food, such as the one of which I have advised you to make use, is a proper one, analysis showing it to be very much like human milk. Upon theory alone, however, I should not venture to take so bold a step as to advise the use of any special food for so delicately organized a being as a human infant. In this instance, however, theory goes hand in hand with the teachings of experience; for, as I have already told you, many persons have before recommended the use of cream, and others have advised that milk sugar be used, and almost all advocate the use of lime water in greater or less quantity. My father, Dr. J. Forsyth Meigs, has for years been in the habit of advising equal parts of milk, cream, lime water and a weak arrow-root water, as a food for infants, and has often had admirable results from its use. Dr. Biedert and others, whose name is legion, recommend increased quantities of fat obtained by the use of diluted cream. Human milk when fresh, if tested with litmus paper, is almost always found to be alkaline in reaction; cow's milk, on the contrary, is almost universally acid. The addition of lime water to cow's milk in the proportions I have advised changes this acid condition to one of alkalinity, and thereby makes it more like human milk, even if the lime water has no ulterior effect which we do not yet comprehend. So you see I have directed nothing absolutely new, taking merely scattered ideas which have come from many quarters and formulating them, experience having taught me that human infants require more fat than is commonly given them, and my analysis having shown that our common foods also fail, partly because they contain too little sugar. One great advance, however, is in formulating precisely in weights and measures how the food should be made, its composition being so simple that almost any woman can easily comprehend and carry out the directions.

In synthetically constructing the food, I have profited first and principally by what experience has taught me, that cow's milk contains too much casein, and that if it is diluted there is too little fat and sugar. Then practice having shown me these difficulties, but not having taught me how to overcome them, my analyses of human milk unfolded to my comprehension its exact composition. Thus you see, having perceived from experience how our present methods fail and in what they are wanting, theory and scientific examination teach how we may at least hope to correct our former errors; for when practical knowledge and theory go hand in hand and explain all the premises, it will be indeed strange if we do not arrive at the truth. If time, which is the great critic and judge in all such matters, deciding these questions with even-handed justice, should show my theory, which is secondary and dependent upon my observations, to be correct, I shall think I have accomplished much towards the saving of human life.

[1] The cream used to make this food happened to contain only 12 per cent. of fat, so that element is in slightly too small quantity. Cream, however, being a variable substance, the amount of fat must always differ.

ORIGINAL ARTICLES.

ON THE GROWTH OF ASPERGILLUS IN THE EAR, WITH A CASE OF THE RARE FORM OF THE PARASITE, THE ASPERGILLUS GLAUCUS.

By CHARLES H. BURNETT, M.D.,

AURAL SURGEON TO THE PRESBYTERIAN HOSPITAL; CONSULTING AURIST TO THE PENNSYLVANIA INSTITUTION FOR THE DEAF AND DUMB, PHILADELPHIA.

The first observations of the growth of a fungus in living animal tissues were made by German and French scientists, in the first half of this century. These men based their statements on what they found in the lungs and air-vesicles of birds. Virchow, too, observed fungi, perhaps the aspergillus, growing in the lungs of man.

The first demonstration of the development of fungi in the ear of living man was given by Mayer[1] and by Paccini.[2] Later cases of the growth of this fungus in the ear and the symptoms of disease caused by it were narrated by Schwartze[3] and Wreden,[4] and

by others in Germany and in this country. In the first volume of the *American Journal of Otology*, 1879, the writer of this article reported twenty cases of the growth of Aspergillus in the human ear, all of them instances of the occurrence of the commoner form, the *A. nigricans*. There are, however, two forms found in the living human ear, both of which cause disease with similar symptoms, viz., the *A. nigricans* and the *A. glaucus*.

The Aspergilli belong to the division of fungi called arthrospores. In the same division are other fungi which become parasites of living man, viz., the Tricophyton, Microsporon, the Achorion, and the Oïdium. The Aspergillus, however, resembling in form ordinary mould, shows a decided or specific tendency to grow in the ear of man. It appears in the ear in one of two forms, either the *A. nigricans* or the *A. glaucus*. These two forms are never found together, so that it is manifest from this alone that the two forms are not different stages of growth of the same fungus. Nor do we find any blending of the two forms, nor any transitions from one to the other, as must be the case if they were two forms of the same plant. Nor is it, in any instance, ordinary mould modified by growing in the human ear, for the fungus taken from the ear and cultivated in a glass jar produces the same form over and over, as was seen in the original piece taken from the ear. Moreover, it is not identical either macroscopically or microscopically with ordinary blue or green mould. From repeated observations—twenty-six cases, some in both ears—I am inclined to regard, with Wreden, the Aspergillus found in the ear of man as the specific aural fungus.

But whether this latter view be correct or not, it is very certain that two distinct kinds of aspergillus are found in the ear of man. The characteristic difference between the two varieties of aspergillus found in the ear of man is seen in the shape and size of the *receptaculum* and the arrangement of the *sterigmata* upon it, these two parts forming the so-called "head," or *sporangium*.

The heads or sporangia of *A. nigricans* are distinguished from those of the rarer form, the *A. glaucus*, by the fact that in the former the sterigmata cover the round receptaculum (B in figure) on all sides, while in the latter form the lower fourth or fifth of the ovoid receptaculum is entirely free from sterigmata (A in the figure). They are distinguishable, therefore, by their shape and not by their color. Of the rarer form, the *A. glaucus*, I have seen but three cases, two of which occurred in my own practice, since the publication of the paper on twenty cases in 1879. Both of these were women, living in the best of hygienic surroundings, and in each both ears were simultaneously affected. The first case has already been reported[1], and the second case has recently been observed, and will be given after a short general consideration of the etiology of the growth of aspergillus in the ear and the otitis excited by it.

Etiology.—The meatus and auditory canal being wounded by pins, or any instrument used for scratching the ear, or the discharge from a boil in the canal being allowed to remain there after the disease has ceased, is an invitation to the spores of the Aspergillus, a saprophyte, to settle upon putrescent animal matter. The same nidus is offered when sweet oil, or any grease, is allowed to become rancid in the ear. The parasite naturally seeks a secluded spot for growing, and hence begins to flourish first upon the inner end of the auditory canal, viz., on the membrana tympani. This excites a myringitis, confined primarily to the dermoid layer of the drum-head and of the inner end of the auditory canal. Though at first this is not a severe inflammation, yet if the Aspergillus is allowed to remain in the ear, the fungus sinks into the fibrous layer of the membrana tympani, the otitis externa becomes more severe, and the parasite, by sinking deeper into the drum-head, finally may enter the drum-cavity, and an otitis media is then set up. This is not ordinarily or rapidly the case, because the successive false membranes of mycelium and epithelium tend to undergo spontaneous detachment from time to time. This is due to the increasing inflammation caused by the growth of the fungus, and the loosening effects of the discharge caused by the disease, but the loosening effect is not sufficient to cause entire removal of the false membrane and all the spores from the ear. At last, if the Aspergillus is not removed and its spores in the ear destroyed by treatment, the drum-membrane ceases to resist the increasing strength of the parasitic vegetable growth, the fungus runs its rootlets and mycelial web into the parenchyma of the delicate membrane, gains the tympanic cavity, and a deeper and more inveterate disease is established. The case of otitis externa, excited by the growth of the rarer form of Aspergillus, the *A. glaucus*, recently observed by the writer, was as follows:

Mrs. J., aged 30, living in the best of hygienic surroundings, has felt for a long time an itching in her ear, to relieve which she has repeatedly and imprudently scratched her auditory canals with hair pins, etc., and irritated the skin of the ear. Within a month both ears have itched more and more, first the left and then the right. The itching was followed by lancinating pains at long intervals, some watery discharge, and a muffled sense of hearing. The walls of the meatus of each ear became swollen and the ears tender in front of tragus.

[1] Transactions of the Pathological Society of Philadelphia, vol. ix., 1879.

On the left side, first attacked, the process of growth in the fungus and the inflammation had been arrested apparently by the patient's forcing, in her manipulation of her ear, some cerumen inward upon the fungus—showing what I have already called attention to, that Aspergillus will not flourish in or upon healthy cerumen. Underneath the ear-wax, however, the perfect Aspergillus was found preserved but arrested in growth.

In the right ear the fungus was in active growth upon the membrana tympani, its favorite habitat, and the inner end of the auditory canal. These parts were deeply injected, sensitive to the gentlest touch, even with cotton on a probe, excoriated, and exuding serum. The sides of the meatus, too, were swollen and the ear in front of tragus sensitive.

Treatment.—The treatment given in detail of this case may be considered as a sketch of that which is best for the cure of Aspergillus in the ear in general. The treatment consisted in first syringing the ears gently with warm water, in order to remove as much as possible of the mycelial false membrane. From each ear there was thus removed a glove-finger cast of the fundus of the auditory canal and membrana tympani. Upon microscopic examination this revealed the *A. glaucus* in perfection. Then into each ear there was gently blown finely pulverized boracic acid, by means of a flexible blow-pipe, made of a foot of black rubber-tubing and a quill-holder at the distal end for conveying the powder into the speculum. The operation was done under perfect illumination by light reflected from the forehead mirror.

The next day the left ear was found very little inflamed and the sense of hearing less muffled. But as some spots of mycelial false membrane were still seen around and upon the drum-head, there was blown into the fundus of the ear, to cover these spots, a powder consisting of

Salicylate of chinoline, ... ʒj.
Boracic acid, ... ʒj.

The right ear was still somewhat inflamed, but less than on the previous day. The hearing was still muffled, and a false membrane was seen to be still over the drum-membrane at spots. The lancinating pains had become less frequent. The ear was syringed, and some pieces of false membrane, which had undergone detachment, came out. Over the still inflamed drum-membrane plain boracic acid, powdered, was blown, as upon the previous visit. Upon the third day the left ear had become normal in every way.

The right ear was very much better and the meatus less occluded by swelling, but the fundus was still swollen and moist with serum, and spots of the fungus were still visible. No pain had been felt since the previous day, but the hearing was still muffled, though less than on the previous day. Again powdered boracic acid was blown into this ear.

On the fourth day the left ear continued well, and the right was very much better in every way. There was, however, still some ulceration of the dermoid layer of the front and upper part of the drum-membrane, but there were no signs of mycelial formation or of discharge. Plain boracic acid powder was blown in over the drum-membrane after it was found that the chinoline-boracic acid powder caused some pain and had been syringed out.

On the fifth day the right membrane had resumed largely its normal contour, the swelling and inflammation being confined to the skin of the auditory canal about the periphery of the membrana tympani. The boracic acid blown in at the previous visit having become a little pasty, it was washed out and fresh boracic acid blown in. The hearing was much less muffled, and the ear began to feel natural once more.

On the sixth day, the right ear was well. Some powdered boracic acid was allowed to remain over both drum-membranes and the inner end of the auditory canal about the membrana tympani, in order to sterilize the region and render it unfit for the growth of the fungus, a plan I always follow now in the treatment of Aspergillus cases after they have become healed.

Until within a year I had found that alcohol, either pure or diluted with water, was the best parasiticide in cases of Aspergillus in the ear. Lately, however, that has been entirely abandoned for the prompter, gentler, and more convenient powder of boracic acid, borax, boracic acid with chinoline, or boracic acid with resorcin, one part of the latter to seven of the former.

The surgeon should blow in the selected powder every day till the parasite ceases to be reproduced and the ear has regained a normal condition. This will require but a few days, whereas the treatment by alcohol instillation used to require sometimes weeks, and always occasioned more or less smarting and, in some instances, pain. The powder insufflations are drying in their tendency, but the fluid treatment in any form, is macerating, and hence rather favors the growth of the fungus, and in many cases seems to favor or provoke an eczema, which is a troublesome complication. The dry treatment, therefore, is eminently successful in otitis externa excited by the growth of Aspergillus in the ear.

Theobald, of Baltimore, recommends as an efficient parasiticide in these cases, a powder of equal parts of boracic acid and oxide of zinc. I have found no powder so efficient as a parasiticide as that consisting of boracic acid and chinoline, in the proportions already given, because both ingredients are known to destroy bacteria and low forms of animal or vegetable life. But if the skin layer of the membrana tympani or of the wall of the auditory canal is broken, the chinoline-boracic acid powder, as given, will cause pain. But in such cases either the chinoline can be lessened or recourse may be had to pure boracic acid, which is nearly as efficient and so bland as to be borne by any ear.

COSMOLINE AND PETROLEUM IN DIPHTHERIA, WHOOPING-COUGH, AND MEASLES.

BY HARVEY L. BYRD, M.D.,
PRESIDENT AND PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN, BALTIMORE MEDICAL COLLEGE, BALTIMORE, MD.

I HAVE been using petroleum locally to the throat for some time past whilst administering cosmoline internally as a remedy in diphtheria; and I beg to

add my testimony now to the value of petroleum and its preparation, both as remedies and prophylactics, in this terrible scourge. I am accustomed to administer cosmoline alone in alternation with lac sulphuris, or in conjunction with it, in eight to fifteen-grain doses of each, according to the age of the child, every two to four hours as required, whilst petroleum is applied to the throat externally. It has been used likewise with quinia, boracic acid, etc., with good results. And while I regard it as the chief factor in procuring relief in diphtheria, the gravity of the disease is such that I have refrained from relying upon its internal use to the exclusion of other remedial agents. I am quite decided in regard to its prophylactic powers, however, and have no hesitation in saying that I feel quite sure that more enlarged experience of the profession will assign it a high place on the list of *preventive*, if not that of *curative* agents also, in diphtheria. I am now accustomed to recommend the administration of cosmoline twice a day to the well children of a family, as soon as called to a case of the disease, and after considerable experience in that way, am pleased to say, with the result of protecting all those from the disease who have taken it in accordance with my directions. Did this statement seem to require the support of cases, it would be an easy matter to extend the length of this paper to several pages with the relation of the instances in which its prophylactic action was indubitably established, or proven so far at least as intelligent and deeply-interested human observation and testimony are capable of deciding anything. It is not deemed inappropriate to add a few words more on the use of cosmoline in two other diseases that affect the same, and anatomically adjacent, parts, and in both of which its action has been highly satisfactory. Those diseases are whooping-cough and measles. Having been satisfied for a long time past that a very large percentage of the diseases to which flesh is heir originate in specific germs, or spores, and that they are without doubt the *fons et origo* of all contagious diseases, I have directed my thoughts and investigations towards neutralizing their action, or the destruction of these extraneous organisms as far as practicable, by the use of appropriate remedies for such purpose.

Experience has demonstrated to me that cosmoline will lessen the violence of the paroxysm in whooping-cough, and loosen, as well as lessen, the mucus quite promptly, and while it may not abate to a considerable extent, it does undoubtedly mitigate, the violence of the attack and shortens the general course of the disease. I feel convinced that it also possesses excellent prophylactic powers in that disease. I have recommended it in repeated instances to the unaffected children in families, after the invasion of the disease, and I think I can say that it has always protected them when given regularly. It allays the cough, and other unpleasant symptoms, in measles, in a satisfactory manner, and I seldom prescribe anything in addition beyond Dover's syrup, or paregoric to procure rest or prevent the bowels from acting too freely. Of its prophylactic power, in this last disease, I am not prepared to speak with much confidence, as I have not tested its action in that way; but reasoning from analogy, as well as from experience in the diseases alluded to above, I should likewise expect satisfactory results from it in that way in an epidemic of measles. The field of usefulness which petroleum and its preparations must occupy, and act a conspicuous part in, in the future is a large one, and it grows more inviting to the scientific physician every day, as the *germ theory* of the origin of diseases becomes more and more *un fait accompli*; and as the arcanum of nature is rapidly yielding up its secrets to the unceasing demands of the great workers in our profession, the time for the fulfilment of this prognostication must be near at hand.

127 N. ARLINGTON AVENUE, September 19, 1882.

HOSPITAL NOTES.

VIENNA GENERAL HOSPITAL.

(Service of PROF. CARL BRAUN.)

CÆSAREAN SECTION FOR CARCINOMA CERVICI UTERI.

(Specially reported for THE MEDICAL NEWS.)

AN interesting case of carcinoma cervicis uteri graviditate has been recently observed and treated in Professor Braun's wards. The patient, a Styrian peasant woman, married, thirty-nine years old, presented herself at the clinic, complaining of unusual pains in her third pregnancy. She stated that her first pregnancy occurred in her nineteenth year, and teminated in the spontaneous delivery of a matured child; her second pregnancy followed in her twenty-ninth year, and resulted in the easy birth of another child at full term.

In January, February, March, and April of the present year, she had alarming hemorrhages from the genitals. The time of the hemorrhage and the quantity of blood lost were very variable. At the same time with this loss of blood, she began to feel sharp cutting pains, radiating from the sacrum to the umbilicus and shooting down the lower extremities into the feet. These pains kept constantly increasing in severity, until within ten weeks she had not been able to sleep for any length of time day nor night. A foul-smelling vaginal discharge was observed about the time of the hemorrhages, which also kept increasing in quantity and fetor up to date of admission into the hospital.

Menstruation ceased in May, according to her own story, and she dated her pregnancy at the latter end of April. Her appetite was exceptionally good, but her bowels were moved only upon the exhibition of a laxative.

The patient was tall, moderately thin and anæmic, with a generally cachectic appearance. Abdominal palpation revealed pregnancy in the eighth lunar month, transverse presentation, second position of the fœtus. The placenta was located upon the right side, anterior wall of the uterus. Vaginal examination revealed the cervix uteri infiltrated around its circumference with carcinoma; the fornix vaginæ also in the same condition. The vaginal portion of the cervix had not disappeared, and the os externum was dilated for one finger. The os was very sensitive and hemorrhage followed the most carefully conducted examination. The diagnosis of carcinoma of the cervix uteri seemed perfectly justified.

Two methods of treatment were suggested: (*a*) hysterostomatomy and version; or (*b*), sectio Cæsarea.

Labor pains were felt for the first time Sept. 28, 7 o'clock A.M., followed immediately by rupture of the

bag of waters. The amniotic fluid was perfectly clear, and the fœtal heart tones were strong and regular. A consultation between privat-docent Von Massari and Dr. Edward Pritzl, second assistant upon the clinic, was at once called, and sectio Cæsarea agreed upon. Three hours later Dr. Pritzl operated upon the woman, choosing Porro's method of supravaginal amputation of the vaginal portion, or hysterotomy, with Müller's modification. The operation lasted one hour. A fœtus of male sex, weighing 2550 grm., with length of 47 cm., was extracted from the uterine cavity in a profoundly asphyxiated condition. The child lived thirty minutes after birth, but was evidently a viable product and apparently eight lunar months old.

Billroth's ecraseur was employed to compress the stump of the cervix and was left in the lower angle of the abdominal incision. The stump was secured in the abdominal wound according to Hegar's extra-peritoneal method. Patient's temperature before and immediately after the operation was 37.6° C. The portion of the uterus removed from the body of the patient was perfectly normal and presented no sign of cancerous invasion upon microscopic investigation.

The patient survived the operation exactly seven days. No consecutive hemorrhage occurred and the abdomen, up to the time of death, remained perfectly concave.

The autopsy conducted in the presence of Professor Braun and his assistants, by Professor Kundrat, was interesting in two particulars. A very slight, diffused peritonitis, with a very small quantity of fluid, was noticed. The carcinoma was found to be confined almost entirely to the fornix vaginæ and only superficially attacking the vaginal portion of the cervix. The narrow, hemorrhagic, ragged edge, taken for the os externum, upon vaginal examination proved to be a carcinomatous stricture of the fornix vaginæ. Metastatic deposits of carcinoma were found in the lungs. A large thrombus was found in the left common iliac vein extending up into the inferior cava.

An interesting fact about operations after Porro's method, with Hegar's extra-peritoneal treatment of the stump, is that after a very variable time the stump sinks deep into the pelvis, and all attachment to the abdominal parietes is ultimately severed.

The anæsthetic employed during the operation is the one Billroth usually uses, and consists of

Chloroform, ...	100 parts.
Absolute alcohol, ...	
Sulphuric ether, of each, . .	30 parts.

MEDICAL PROGRESS.

A Case of Gastrostomy.—On the 4th inst., Mr. Francis Mason performed the first step of this operation at St. Thomas's Hospital, on a man aged about sixty, for rapidly increasing carcinoma of the left tonsil and neighboring parts. An incision about two inches and a half in length was made parallel with the costal cartilages of the left side and about a finger's breadth from their margin, the lower end of which was about opposite the ninth rib. The structures of the abdominal wall were divided until the peritoneum was reached, which was carefully opened. The forefinger and thumb of the left hand were then introduced, and, guided by the left lobe of the liver, the stomach was readily grasped and brought out slightly at the wound. Great care was taken, both before and after the peritoneal cavity was opened, to arrest all hemorrhage with catgut ligatures. The parietal layer of the peritoneum was accurately adjusted in contact with the visceral layer of the stomach, and the two surfaces were kept in contact by passing a carbolized silk thread through the whole thickness of the abdominal parietes, and also through the serous and muscular walls of the stomach; four such stitches were employed. Two other deep sutures were made to transfix each end of the wound only, care being taken to include the peritoneum. Lastly, a stitch was passed through the serous and muscular walls of the stomach itself, and was left hanging from the wound to be used as a guide for the future opening of the stomach. Superficial stitches were used to unite the edges of the skin wound. The operation was performed throughout under the carbolic spray, and dressed with the usual antiseptic precautions. The patient was very comfortable during the remainder of the day and passed a good night, but on the following day he complained of hiccough, which distressed him a good deal, giving rise to a painful dragging in the region of the wound. This was allayed by the administration of small doses of medicine containing dilute hydrocyanic acid; beyond this nothing but ice in small quantities, and afterwards, at the patient's special request, a small quantity of tea was allowed by the mouth, he being fed by nutrient enemata. On the second day there was some difficulty of breathing, and he spoke of a sensation of not being able to cough up phlegm and other accumulations from the air-passages. Still his temperature kept fairly normal. On the third day, however, the temperature rose to 101°, and in the afternoon his dyspnœa became so urgent that it was thought necessary to perform tracheotomy as a *dernier ressort*. This operation was performed by Mr. Duncan, the house-surgeon, with some relief, but, in two or three hours after, the patient died, apparently from exhaustion, exactly seventy-two hours after the gastrostomy was performed. At the post-mortem examination, it was found that adhesion of moderate firmness had taken place between the visceral and parietal layers of the peritoneum at the site of the operation, but not sufficiently firm to heal. The mucous surface of the stomach had not been perforated, and there was no general peritonitis. It may be added that the patient inhaled ether during the operation, which may possibly account for the dyspnœa, and also that he had some symptoms of carbolic poisoning, as indicated by the condition of the urine during life.—*Lancet*, October 14, 1882.

Sudden Death in Gastric Ulcer from Entrance of Air into the Bloodvessels.—Jurgensen has recently met with two cases of this nature, one of which he describes with considerable detail. A woman aged 49, had for years suffered from the symptoms of gastric ulcer, particularly from repeated exhausting hemorrhages from the stomach, by which she was reduced to the last degree of anæmia; she died suddenly. At the autopsy, an ulcer 6 to 7 centimetres in diameter was found on the posterior wall of the stomach; the pancreas, duodenum, and left kidney, were all adherent to the ulcer, on the surface of which there was found a large vein, probably the splenic, with a slit-like opening in its walls about one centimetre in length. The stomach was filled with clots: the veins of the liver and spleen were filled with air. Air was also found in the veins of the stomach, in the jugular veins, pericardium, heart cavities, sub-serous cardiac tissue, and pulmonary bloodvessels. There was also subplural and sub-intestino peritoneal emphysema.—*Deutsches Arch. für klin. Med.*, August, 1882.

Comparative Sizes of Organs.—Drs. H. P. Bowditch and F. A. Harris give the following comparative measurements in their report on the best method of collecting data at autopsies:

1. Before the period of puberty the aorta is *smaller* than the pulmonary artery, after this period the rela-

tion begins to be reversed, and in advanced life the aorta is always *larger* than the pulmonary artery.

2. The aorta and pulmonary artery are absolutely smaller in the female than in the male, but relatively to the length of the body there is scarcely any difference between the circumference of the arteries in the two sexes, while the heart in females is absolutely as well as relatively a little smaller than in males.

3. In adult males the volume of the lungs is greater than that of the liver; in adult females the reverse seems to be true.

4. In men, the volume of the two kidneys is nearly equal to that of the heart; in children it is greater.

5. Children have a relatively larger intestinal canal than adults.

6. A sudden increase in the size of the heart occurs at the period of puberty.

7. The iliac arteries diminish in size during the first three months of life.

8. The cancerous diathesis is, in the majority of cases, associated with a large and powerful heart and capacious arteries, but a relatively small pulmonary artery, small lungs, well-developed bones and muscles, and tolerably abundant adipose tissue.

9. Pulmonary tuberculosis is often associated with an unusually small heart.

10. In constitutional rachitis the heart is generally large and well developed; the arteries are also large. —*Boston Med. and Surg. Journ.*, Oct. 19, 1882.

LIGATURE OF THE INNOMINATA.—The full details of Mr. Thompson's case of ligature of the innominata artery for aneurism, whose progress and result have been given in our columns, is published in the *British Medical Journal* for October 14, 1882. This case was the first in which Listerism and animal ligature were combined in deligation of the arteria innominata. Through some misfortune, the unclosed portion of the wound ceased to be aseptic after the eleventh day, and to that Mr. Thompson attributes the regrettable result; but his experience of this case leads him to say that, with an antiseptic condition of wound, and with a broad animal ligature, the operation is not only feasible, but justifiable; and that, personally, he should not hesitate to do it again, and with good hope of success.

TREATMENT OF ABSCESS OF THE LIVER BY LARGE OPENINGS.—At the meeting of the Académie de Médecine held October 3, 1882, M. J. ROCHARD referred to a communication which he had made in October, 1880, in reference to the method of treating abscess of the liver employed by the physicians of Shanghai: the method consists in freely opening the abscess after the diagnosis has been confirmed by an exploratory puncture, using the needle as a director to the incision, and then employing Lister's method of dressings. Since then M. Rochard has received numerous communications which have served to strengthen his confidence in the value of this plan of treating hepatic abscess, among others, two recent cases. Of these, the first was that of a mulatto aged 23 years, operated upon by Dr. Scotland, nearly two litres of pus being drawn off: improvement was immediate and cure rapid. The second case occurred under the care of Dr. Bernard in a girl aged 19 years, in whom free incision was employed after aspiration had failed to give any relief: a cure also resulted in this case.—*Gaz. Médicale de Paris*, October 7, 1882.

THE EFFECTS OF BROMIDE OF ETHYLE IN HYSTERIA AND EPILEPSY.—DR. BOURNEVILLE, physician to the Bicêtre Asylum, after several experiments to ascertain the effects of the bromide of ethyle in cases of hysteria and epilepsy, has come to the following conclusions: 1. The dilation of the pupil at the commencement of the inhalations of the bromide of ethyle is not constant. 2. The complete muscular resolution is exceptional. 3. Anæsthesia is produced in different degrees, according to the subjects experimented on. 4. The temperature, the secretions, and the general state of the patient do not appear to undergo any modification. 5. The pulse and the respiration are slightly accelerated. 6. Trembling of the limbs in a more or less marked degree during the inhalation may be produced, but it does not persist after the cessation of the inhalation. 7. Hysterical attacks are in general easily arrested by the bromide of ethyle. 8. Epileptic fits may sometimes be arrested by administering the medicine at the commencement of the tonic stage; more frequently, however, the inhalations produce no effect. 9. In epilepsy the regular employment of the bromide of ethyle, administered by inhalations daily during one or two months, greatly diminishes the frequency of the attacks.—*Lancet*, October 14, 1882.

TRAUMATIC SPASM OF THE ŒSOPHAGUS.—In the *Union Médicale* for October 12, 1882, M. COURTADE reports a case which seems to show that a blow on the head or thorax in an individual showing before then no disturbance of the nervous system may be followed by persistent spasm of the œsophagus. In the case reported bromide of potassium in large doses and repeated catheterization were sufficient to produce a cure.

OSTEOMALACIA IN CHILDREN.—DR. H. REHN believes that this disease is not as rare in children as has been supposed. He reported, in the recent Congress of German Naturalists at Eisenach, the case of a female child in whom there was marked flexibility of the bones of the extremities and thorax; both scapulæ were thin and bent, as well as the clavicles, the humerus, radius, and ulna. Death occurred from bronchitis, and Recklinghausen confirmed the diagnosis. Five other cases are also mentioned, from which he draws the following summary of the characteristic symptoms of this disease: Flexibility of the bones and pain on motion; absence of fever and indisposition to move; deposit of phosphates in the urine; chronic course; majority of cases females, as is the case in adults. Two of five cases under his care recovered. This disease can be attributed to faulty nourishment, particularly to absence or insufficiency of lime salts.—*All. Wiener Med. Zeit.*, October 3, 1882.

NEW METHOD OF DILATATION OF THE EUSTACHIAN TUBE BY ELECTROLYSIS.—M. J. MERCIÉ has been applying with success, in the clinic of DR. DÉSARÈNES, for the dilatation of strictures of the Eustachian tube, the method employed by Dr. Gorecki in the treatment of nasal and urethral strictures. The method consists in first introducing an ordinary Eustachian catheter and passing through it, while the patient pronounces the syllable *mi*, a fine bougie, and allowing it to remain in position five or ten minutes; this process is repeated until it has been found by inspection that the sound has reached the middle ear. When the tube has been dilated to this extent, the elastic sound is replaced by a flexible metal one connected with the negative pole of a weak battery, while a disk of metal connected with the positive pole is placed in the external auditory canal. This procedure is unaccompanied by any danger, if the current is weak and great care is observed in inserting the metal sound; and although it has not been very frequently employed, the success was such in those instances as to encourage its subsequent use.—*Rev. de Thérapeutique* Oct. 1, 1882.

A NEW TEST FOR ALBUMEN IN THE URINE.—When an albuminous urine is treated with a saturated solution of common salt, not the slightest reaction takes place; but if the brine be slightly acidulated with hydrochloric acid, according to DR. WM. ROBERTS, the albumen is thrown down as a dense white cloud. This reaction constitutes a most delicate test for albumen in the urine. The best degree of acidulation for this purpose is obtained with about 5 per cent. of the dilute hydrochloric acid of the Pharmacopœia. A little more or a little less acid makes no appreciable difference in the sensitiveness of the test. Common salt dissolves in about two and a half times its weight of water at 60° F., and increase of temperature does not sensibly increase its solubility. The salt of commerce is always more or less dirty, and the solution requires filtration to fit it for use as a test. The salt solution should be fully saturated, otherwise the observer is apt to be led into error. In preparing the test with our common English measure the readiest plan is to mix a fluidounce of dilute hydrochloric acid with a pint of water, and to saturate this with common salt, and filter. Dilute hydrochloric acid may be replaced by dilute sulphuric, dilute nitric, or dilute phosphoric acid. All these acids are of the same saturating strength in the British Pharmacopœia, and all of them yield with saturated salt solution an equally sensitive reagent for albumen. Even acetic acid may be used, but the delicacy of the test in that case is not quite so great as when it is prepared with one of the mineral acids. The method of applying the briny test is similar to that followed with nitric acid. A portion of the suspected urine is placed in a test-tube, the test-tube is then held very much aslant, and the salt solution is allowed to trickle along the sides of the tube to the bottom, so that it may form a distinct layer below the urine. If albumen be present, a white cloudy zone appears at the junction of the two fluids. Or the proceeding may be reversed. The salt solution may be first introduced into the test-tube, and then the urine added with the same precautions as before, so as to obtain two distinct layers, one above the other, in the test-tube. It is important to be aware that the precipitation of albumen by acidulated brine is not due to a true coagulation. In this respect the brine test differs from nitric acid and boiling. In the two latter cases the albumen is transformed into the insoluble modification, which is known as "coagulated albumen." But when albumen is thrown down from urine by accidulated brine, the precipitate is not insoluble; on the contrary, it is redissolved by free addition of water, or even by free addition of the albuminous urine itself. It is therefore essential to the efficient application of the test that the salt solution should be in excess at the point of expected reaction. This end is obviously secured in the above described methods of testing. In point of delicacy the salt test stands on a par with nitric acid. The minutest trace of albumen detectable in the urine by nitric acid is also detectable with equal ease by acidulated brine. In high-colored urine the brine test is distinctly superior. —*Lancet*, October 14, 1882.

EXCISION OF MECKEL'S GANGLION AND THE SUPERIOR MAXILLARY NERVE.—Last week at the General Hospital, Birmingham, MR. T. P. CHAVASSE excised the superior maxillary nerve at its exit from the foramen rotundum to its facial termination, Meckel's ganglion being removed. The spheno-palatine fossa was reached by trephining the anterior and posterior walls of the antrum, and tracing back the infra-orbital nerve. The operation was performed for obstinate neuralgia of fourteen years' standing, in a man aged fifty. The wound has virtually healed, and there has been no recurrence of the pain. This operation has been previously performed by James R. Wood and Carnochan, of New York, and, we believe, a very similar one was once before performed in England.—*British Medical Journal*, October 14, 1882.

TREATMENT OF DIABETES WITH BROMIDE OF POTASSIUM.—In our numbers for September 2, and October 21, we alluded to the above treatment of diabetes advocated by Dr. Felizet. In the current number of the *Journal de Médecine de Paris* (October 7), the editor, M. BERGERON, announces that he has just seen the sugar entirely disappear from the urine of a diabetic patient under fifteen days' treatment, four grammes of the bromide being taken each day.

TREATMENT OF CATARRHAL ANGINA.—Under this term, DR. FRAENKEL (*Verhandl. der Berl. Med. Gesellsch.*, Band xii. p. 239) understands mainly that form called tonsillitis lacunaris, a disease which, he says, in the great majority of cases, subsides without treatment, so that our object can only be to shorten or render it less severe. The use of astringents, such as nitrate of silver, he considers useless, as the disease lies mainly in the crypts of the tonsils, which the astringent does not reach. The same is true of gargles and of inhalations, while the former, in addition, frequently of themselves cause unpleasant sensations in the throat. At the same time, it must not be understood from this that the throat is to be left dry in this affection. The use of emollients gives frequently much relief. Dr. Fraenkel has tried submucous injections of a carbolic acid solution, so as to be sure of reaching the crypts, but has seen no benefit from them. Among internal remedies for the disease, Dr. Fraenkel has seen no good result from chlorate of potash, which he has found most useful in certain forms of stomatitis. Of guaiacum, recommended strongly by Dr. Morell Mackenzie, he has had no experience, nor has he had any experience of tincture of aconite, which last remedy, he appears to think, has been borrowed from homœopathic sources by English physicians. Ice and cold applications are to many most grateful, while to others they are absolutely intolerable. For some time, Dr. Fraenkel has treated all his cases either with quinine or with salicylate of sodium. Of fifteen cases treated with large doses of quinine, not one has lasted longer than forty-eight hours, the usual average being from two to five days, he believes. Dr. Fraenkel himself has suffered frequently from this disease, and has never so quickly recovered from any treatment as from this. He takes three doses of about four grains of quinine within an hour at night. Notwithstanding, however, that quinine so shortens the disease, it does not in certain cases prevent the formation of peritonsillar abscess. The *rationale* of the action of quinine Dr. Fraenkel does not pretend fully to understand. Its antiphlogistic antifermentative actions seem scarcely enough to explain it, for salicylic acid seems to have no such favorable action, and while tonsillitis is well known to be infectious, it can scarcely be called one of the infectious diseases proper, for one attack rather predisposes to others. He recommends the treatment to the attention of physicians, as each can have only a limited number of such cases under his care.—*London Medical Record*, October 15, 1882.

BROMINE AS A DISINFECTANT.—In a paper on the above subject, read at the Berlin Apothecaries' Congress, DR. FRANKE, of Charlottenburg, called attention to the fact that the difference between disinfection and deodorization has only recently been appreciated by the general public. It is, however, now known that many inodorous substances are highly dangerous communicators of disease. The researches of Dr. Koch

have brought to light the fact that a number of so-called disinfectants which have been employed for many years are quite insufficient preservatives against many kinds of disease-germs. Thus of late the search after new and reliable disinfectants has been actively carried on. Bromine has materially decreased in price since its production on a large scale at Stassfurt has made it an article of commerce, and Dr. Franke claims to have succeeded in obviating the difficulties which its strong corrosive qualities and other circumstances placed in the way of its general adoption. By the employment of organic acid combinations of alkalies he has succeeded in obtaining in a fluid form eight-tenths of the volume of bromine. The evaporation of the bromine is, he states, thereby considerably retarded, and a permanent disinfection facilitated. For mere deodorization a comparatively small quantity of bromine suffices, while for real disinfection a greater bulk is required. Experiments made by the Berlin sanitary officials have resulted in the fact being established that three and a half ounces of bromine could disinfect a space of 918 cubic feet against the most inveterate forms of infection, for removing which sulphurous acid had proved unsuccessful. Other experiments showed that for simple deodorization one-third of an ounce of bromine, hung up high, is sufficient for a space of 7,000 cubic feet. With reference to the use of bromine in the practice of medicine, he remarked that in a gaseous form bromine could be introduced into parts of the body not accessible to any other corrosive agent. In connection with the corrosive properties of bromine, he stated that petroleum had been accidentally discovered to be a cure for burns caused by bromine in a fluid state.—*Lancet*, October 14, 1882.

UNSUCCESSFUL PORRO OPERATION FOR UTERINE FIBROID.—L. PROCHOWNICK reports a case of removal of the uterus by Porro's operation for fibroid tumor, in which death occurred on the third day from septicæmia.—*Deutsche Med. Woch.*, Sept. 30, 1882.

POISONING BY MALE FERN.—A death is reported from Columbo, Ceylon, where a gentleman was prescribed three-quarters of an ounce of ethereal extract of male fern and a drachm and a half of Pulv. Kamalæ, for the cure of tape-worm, and the dose was repeated in four hours. The patient sank, with symptoms resembling those of choleraic diarrhœa. The necropsy revealed congestion of the stomach, with ecchymoses beneath the mucous membrane, and small clots of blood upon the mucous surface of that organ. There were similar patches in both the small and large intestines. Indeed, there was clear evidence of the administration of an irritant poison. The prescription is said to have been one copied by the medical attendant of the deceased gentleman from a work of repute, where the quantity of extract of male fern is apparently a misprint.—*British Medical Journal*, Oct. 14, 1882.

LESIONS OF THE TEETH IN LOCOMOTOR ATAXY.—At the meeting of the French Association for the Advancement of Science, on August 30, a communication was made by M. Th. David upon lesions of the teeth found in locomotor ataxy. The paper was based upon the observation of a single case, and the following are the most important of the conclusions arrived at from an attentive study of it. The alteration consisted of a rapid decay of the anterior part of the crown of almost all the teeth. The altered substance assumed the consistence of touchwood and a reddish color. The enamel still retained its polish, but not its hardness. Beneath those parts the pulp had produced a new layer of secondary dentine, and in most of the front teeth the pulp-cavity was filled up. These alterations had nothing in common with caries, and must be referred to nutritive disturbance resulting from the lesion of the central nervous system. The changes are analogous to those which have already been observed to take place in the nails in the course of locomotor ataxy; they would thus establish a pathological relationship between organs already connected by a common epithelial origin. Locally, these alterations recognize for their immediate cause a functional disturbance or a lesion of the dental pulp. The atrophy which has been shown to exist would be quite comparable to that which is observed in the eye under similar circumstances. Whence the final conclusion that we must attribute to the dental pulp the physiological significance of a sensory organ.—*Medical Times and Gazette*, October 14, 1882.

PERFORATION OF THE ŒSOPHAGUS BY A PIECE OF GLASS: EXTRACTION THROUGH THE ANTERIOR ABDOMINAL WALL.—PROF. KUESTER reports in the *Medizinish-chirurgisches Centralblatt* for September 29, the remarkable case of a man who accidentally swallowed a small triangular piece of glass, which became fixed in the cardiac region, and for a year and a half resisted all attempts at extraction, caused the most intense pain and spasms of coughing, and rendered swallowing almost impossible. Frequent hypodermic injections of chloroform in the epigastric region to allay pain resulted in a slough and abscess, through which the piece of glass was discharged. Complete recovery ultimately resulted.

NEW METHOD OF PREPARING BLISTERS.—M. LIMOUSIN (*Rép. de Pharm.*, June, 1882) has devised a new form of blister, with a view to afford a greater variety of choice in degree and kind of vesication, and also with a view to preserve the ready-made blister. He spreads a thin layer of ordinary blistering cerate upon strong, thin, unsized paper, and covers it with the same. The vesicating layer is about one and a half millimetres in thickness, and one of its surfaces is camphorated. When using the blister, its outline is marked upon the paper covering it; it is then cut off and applied to the part by means of a piece of adhesive plaster. The covering paper may be readily removed, both from the plain and from the camphorated side, by means of a wet sponge. If the physician order a blister covered with oiled paper, it is only necessary to saturate the covering paper with oil. The same process may be also used for the preparation of other plasters. *London Medical Record*, October 15, 1882.

A READY METHOD FOR THE VOLUMETRIC ESTIMATION OF ALBUMEN IN THE URINE.—MR. GUY NEVILLE STEPHEN recommends for this purpose a method suggested by Tauret, of Troyes, as far back as 1872. The basis of this method is the precipitation of albumen by the double iodide of mercury and potassium, and it is equally applicable both for testing for and estimating albumen. In urine loaded with urates a precipitate of uric acid may be thrown down when the acetic acid is added, but merely diluting the urine with water will cause it to disappear. Mucus, too, if present, may also be precipitated by the acid, but will give no trouble, as it is quite different in appearance to the precipitate of albumen, and will have dropped to the bottom before the solution is added; and, lastly, if the acetic acid be not used in sufficient quantity to make the urine decidedly acid, urea may be thrown down by the after addition of the potassio-mercuric iodide.

Estimation.—The process for this is extremely simple and rapid, and only requires that the solution employed be of known strength, and that the quantity used both of it and of the acid and urine be carefully

noted, and the complete precipitation of the albumen proved by a second solution. Besides the solution and acid, a glass, graduated in cubic centimetres, a pipette giving drops of five centigrammes, and a few glass stirrers, are all that is required. For the precipitating solution the formula is—potassii iodidi, 3 grms. 22; hydrargyri bichloridi, 1 grm. 35; aquæ destillatæ, q. s. ad. 100 cc. For the confirmatory solution—hydrargyri bichloridi, 1 grm.; aquæ destillatæ, q. s. ad. 100 cc. One drop of the precipitating solution given by a pipette of the above size precipitates 0.005 of albumen; so that so many drops as it takes to precipitate all the albumen, so many times 0.005 of albumen must there have been in solution. To save trouble in calculation, the same quantity of urine should always be taken, and the best quantity to take is 10 cc., as then the number of drops of the solution that it takes to precipitate all the albumen in this quantity of urine represents so many half grammes of albumen to the litre. Take then 10 cc. of urine, and add two of acetic acid, and stir with a glass rod; then add the precipitate solution drop by drop, stirring carefully each time, until the precipitate is no longer redissolved in the albumen in excess—*i. e.*, as yet unaffected by the reagent; then after each drop of the solution put a drop of the urine on a porcelain dish and watch if a yellowish-red color appears on adding a minute drop of the confirmatory solution. As soon as it does, all the albumen is precipitated and the process is finished, and the amount of albumen per litre will be at once arrived at by taking the number of drops employed of the precipitating solution, substracting three as having been used in excess to make the yellow color perfectly clear, and then considering the rest as so many half grammes.

The chemical reactions and data upon which the above depends are $2KI+HgCl=HgIKI+KCl$. When the double iodide of mercury and potassium thus formed is added to albuminous urine sufficiently acidified, all the albumen is precipitated in combination with the mercury and iodide of the reagent, in the proportion of the equivalent of HgIKI, weighing 393 to 1 equivalent of albumen, $C_{68}H_{70}Az_{11}O_{33}$, weighing 1004, while the potassium is taken up by the acid of the urine. As long as any albumen remains in solution the double iodide of mercury and potassium will not form red iodide of mercury when bichloride of mercury is added to it, but it does so as soon as all the albumen is precipitated. The solution formulated above is such that every drop of 0 grm. .05 contains 0 grm. .00196 of HgIKI, and therefore in accordance with the equivalents given will precipitate .005 of albumen.—*Lancet*, Oct. 14, 1882.

Rare Complications of Chronic Gonorrhœa in the Male.—Dr. Vagda has written on this subject in the last two numbers of the *Wiener med. Woch.* (37 and 38). The essence of what he has to say comes to this: Owing to the prolonged irritation of the chronic discharge, the epithelial and connective tissues may get hypertrophied, so that the former may become from four to twelve times its normal thickness, whilst the latter may form outgrowths, which in the early stage are non-vascular. The neoplastic epithelial formation, by pressure of its own elements *inter se*, may lead to the total destruction of the normal cylindrical layer of cells. This overgrowth of epithelia may accumulate in clumps anywhere, but has a predilection for the hypertrophied papillæ and warts, where it mounts their summits and descends into the clefts and fissures between them. The warts may be found in any part of the urethra, and are very small, conical, brush-shaped, or clavate growths, which are either enlarged normal papillæ or are outgrowths from the newly-formed connective tissue. Should these warty excrescences themselves begin to grow, they may give rise to secondary offshoots and become vascular, and then are analogous to the gonorrhœal warts so frequently seen on the prepuce or glans penis and just within the external orifice of the urethra.—*Med. Times and Gaz.*, Oct. 14, 1882.

New Antiseptics for Surgical Use.—Certain inconveniences and disadvantages attending the use of carbolic acid spray in dressing wounds have led to a general search for acceptable substitutes. One of the most promising is the use of substances which are volatile as well as of antiseptic nature, such as eucalyptol, cajeput, terebene, and peppermint, by means of which a wound may be kept, if necessary, in an antiseptic atmosphere not merely while being dressed, but at all times.

At the late annual meeting of the British Medical Association Mr. A. W. Mayo Robson described a series of experiments made by him to test the efficiency of atmospheres charged with such volatile antiseptics in preventing the development of life in putrescible fluids, the results being exceedingly encouraging. Flasks of sterilized hay infusion suspended in large, wide-mouthed, open jars, into which a little eucalyptus oil, cajeput oil, or the like, had been poured, remained clear, while flasks of the same infusion briefly exposed to ordinary air and then covered with cotton wool began to lose clearness and to scum over within a few hours. Altogether the results were thought to indicate that at ordinary temperatures air saturated with vapors of the class named was fatal to the germs of bacteria and micrococci, and probably also to the germs of fevers and other infectious diseases. As the vapors tested are not unpleasant or injurious when breathed, it is to be hoped that practical tests in hospital wards will confirm the promise of Mr. Robson's experiments. As eucalyptol—derived from the common eucalyptus—is abundant and cheap, it has been selected for further tests. Several surgeons have taken part in these tests, and the results are decidedly encouraging. When the vapor is used during surgical operations a bellows is employed to discharge air charged with it upon the spot exposed. The air is first drawn through a vessel filled with cotton wool, then through others filled with pumice stone over which a small quantity of eucalyptol has been poured. The emerging air is thus loaded with invisible particles of the antiseptic, which seem to be capable of destroying any vestiges of germ-life which may have been drawn in from the surrounding atmosphere. This is a pleasanter method than Lister's or the boroglyceride treatment of Professor Barff.

Not less promising is the turf-mould dressing of Dr. Neuber, of Kiel, the result of investigations of the antiseptic qualities of turf-mould made by him during the past two years. The fibrous and friable character of turf, and its lightness, softness, and elasticity, make this substance much neater and more comfortable than "dry earth" as a surgical dressing; and it seems also to have much greater antiseptic power. The mould, reduced to powder, is inclosed in bags of carbolized gauze, and simply bound upon the wound, which has previously been washed with a carbolic or other antiseptic lotion. This dressing has been used by Professor Esmarch in fifty-five cases, most of them severe operations, with wonderfully good results. In thirty-one cases there was no fever, and in only five cases was it necessary to remove the dressing, owing to either local or general disturbance. The chief advantages claimed for this dressing are its great absorbent power, its tendency to prevent the formation of putrefactive products; the easy adaptability of the turf pads to the surfaces of the body and limbs; and its cheapness, the cost being about one-ninth that of the Listerian dressings. For use

in public hospitals and in private practice among the poor, the element of economy is a very important one.

Another great advantage, if the apparent virtues of turf-mould are confirmed by wide experience, will arise from the circumstance that it is everywhere obtainable. Dr. Neuber's attention was drawn to its possible merits by the appearance in the clinic of Professor Esmarch of a patient who reported that his arm had been badly hurt eight or ten days before while he was at work upon a moor. The injured arm had been simply covered with mould and protected by a rude wooden splint. The patient appeared to be in good general health. When the primitive dressing was removed the surgeons were astonished to find that with an extensive laceration of the soft parts of the arm, a rupture of the wrist-joint, and a fracture of both bones of the forearm, the wound was free from suppuration—in some parts already united by first intention, in others granulating in a satisfactory manner. The physical condition of the patient and the purity of the country air may have contributed somewhat to the healthy condition of the seemingly neglected wound; but, as subsequent trials proved, the main protection came from the antiseptic mould; a dressing most easily obtained where other antiseptics are to be had with difficulty. Country practitioners and workmen on railways and other works away from surgeons and surgical appliances, will do well to bear this fact in mind. Of course, care must be exercised in selecting turf-mould for such purposes from spots not likely to be subject to local contaminations, else it might serve to introduce the very germ which it is sought to avoid and exclude.—*Scientific American*, October 21, 1882.

TREATMENT OF RANULA.—In the *Gazette des Hôpitaux*, No. 113, an example is related of the successful treatment of a ranula by M. Anger's method, which consists in injecting by means of a Pravaz syringe one or two drops of deliquescent chloride of zinc, without having previously discharged the contents of the cyst. Considerable inflammation followed the injection, but without phlegmon or gangrene. The sac became retracted, its liquid contents having been absorbed. Whether a relapse may not take place cannot be certainly stated; but this has not occurred in several other cases that have been thus operated upon. Against the objection that the procedure causes sharp inflammation and is very painful, have to be set its facility and efficacy.—*Med. Times and Gaz.*, Oct. 14, 1882.

THE INDICATIONS FOR NEPHRECTOMY.—DR. LUIGI BRICHETTI (*Gaz. degli Ospitali*, Aug. 9) thus sums up what he considers the chief indications for nephrectomy: 1. Certain wounds of one or both kidneys; 2. Movable kidney, complicated with neuralgia; 3. Tumors of the kidney, hydro- or pyonephrosis; 4. Renal calculi; 5. Parasites; 6. Certain affections of the ureters. In the majority of cases of pyonephritis, the author, however, would prefer large incisions into the organ, kept open with drainage-tubes, rather than its removal, especially after gunshot wounds.—*London Medical Record*, October 15, 1882.

THE TREATMENT OF SYPHILIS BY SUBCUTANEOUS INJECTION OF MERCURIAL SALTS.—LETNIK (*Wratsch*) believes that the time is not far distant when all other modes of treating syphilis will be displaced by the subcutaneous injection of mercury. In the cases of prostitutes, who frequently, in hospital, refuse to submit to the ordinary course of treatment, this method of administering the remedy is almost indispensable. Its advantages are stated as follows: 1. The dose may be more nicely graduated. 2. Baths and frequent changes of linen are dispensed with in the treatment of the poor. 3. The rapid disappearance of fresh syphilitic symptoms, often after only six or eight injections. 4. The patient will possibly be able to continue his usual occupation. 5. The whole course of treatment is shortened. Taking the results of various authors in 1892 cases (during 5 years), Letnik finds that the average duration of various modes of treatment is as follows: *α*. Internal treatment, 78⅓ days. *β*. Inunction course, 56 days. *γ*. Subcutaneous injection course, 32 days—the length of the latter course of treatment being less than half that in which the remedy is given by the mouth. 6. Stomatitis is remarkably rare. 7. The general health is improved rather than injured, although no change is made in the diet. Letnik has treated thus 210 cases. The treatment was abandoned only five times, three times in much reduced patients, in whom severe nervous symptoms were observed after each injection, and twice in cases of rupia syphilit., where no benefit was attained. Whilst 172 patients exhibited the malady under the form of exanthemata or condylomata, 32 were suffering from advanced syphilis. The number of injections in any one case varied from 20 (minimum) to 45 (maximum). The salts employed were chloride of mercury with sodium chloride, corrosive sublimate ($HgCl_2$) with morphia, and bicyanide of mercury. The pain produced by the first-named solution lasted about 15 minutes, while that caused by the others remained for half an hour. The local induration after injection of the mercury-sodium salt lasted at most 5 or 6 days; that after the cyanide 20 days or more. No experiments with mercury albuminate and its allies were made.—*Edinburgh Medical Journal*, October, 1882.

CASE OF HEPATIC ABSCESS TREATED BY ANTISEPTIC INCISION: CURE.—PROF. KUESTER reports the case of a man, aged fifty-eight years, with a painful, fluctuating tumor of the hepatic region, which, on aspiration, proved to be an abscess of the liver. As it became superficial, and was evidently on the point of opening spontaneously, it was opened antiseptically, and the cavity treated by drainage. The case was cured.—*Med.-chir. Centralb.*, Oct. 6, 1882.

OCULAR CHANGES IN HEPATIC DISEASE.—Hemorrhages into the retina have been found in catarrhal jaundice, gall-stones, carcinoma, cirrhosis, abscess, acute atrophy, phosphorus poisoning, dropsy of the gall-bladder, and in pneumonia accompanied by icterus. Such extravasations are by no means always of bad omen, seeing that they may accompany a harmless catarrh, provided this be attended by jaundice. In a case of acute yellow atrophy due to phosphorus poisoning, Litten (*Wiener med. Woch.*, No. 39) found, by the side of multiple fresh hemorrhages into both retinæ, certain white areas situate in the granular layer, which microscopically showed fatty degeneration with tufts of tyrosin and granular spheres (? leucin). The blood capillaries had undergone marked fatty metamorphosis. In two cases of atrophic cirrhosis, Litten observed simultaneous pigmentary degeneration of the retina, which in one instance had developed after the liver disease had already been of long standing, whilst in the other case it was found in the course of the first year. The formation of pigment may extend very rapidly. Hemeralopia (night-blindness) sometimes accompanied a hypertrophic or atrophic hepatic cirrhosis without any sign of organic change in the structures of the eye. Immediately after the tapping of a considerable amount of ascites a neuro-retinitis developed itself, with slight swelling of the optic disk and exudation into the tissues and around the vessels.—*Med. Times and Gazette*, October 14, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, NOVEMBER 4, 1882.

IS CONSUMPTION CONTAGIOUS?

THE infective nature of tubercle has been a subject of unremitting investigation since the experiments of Villemin were first promulgated. According to these observations, when tubercle was injected under the skin or thrown into the cavities of rabbits, general tuberculosis followed. But it was soon ascertained that rabbits are scrofulous subjects—so to speak—in whom suppurative inflammation of any kind induces tuberculosis. Notwithstanding these adverse observations, there was a growing conviction that something of a specific nature existed in genuine tubercle. Then Klebs, and afterwards Aufrecht, announced the discovery of the tubercle parasite. Their descriptions of the organism did not agree, and they and others who have isolated a supposed infective principle of tubercle, differ from Koch in the description of the *bacillus tuberculosis*. If the last mentioned be the true, specific contagium, our task is much simplified. The organism producing tuberculosis being defined, there is no longer any doubt how this disease may be propagated. Just as a certain culture soil is necessary for the growth of the bacillus, so a state of the human organism is necessary to the successful propagation of tuberculous matter.

Whether the existence of a bacillus tuberculosis be admitted or not, it is clear that, from the clinical standpoint, a contagious principle is rendered probable by numerous apparent cases of transmission. Amongst others Dr. Webb, of this city, has reported several examples of the supposed communication of consumption. M. Leudet has studied this question in fifty-six households belonging to the better classes. Thus in fifteen examples the husband was tuberculous and the wife healthy at the time of marriage, and for some time afterwards, and in forty-one the female only was thus affected.

In the first series, five of the wives were attacked subsequently with tuberculosis, one had Pott's disease followed in six years by phthisis; one had a sister, and another an aunt fall victims to consumption. In the second series of forty-one, three of the husbands became tuberculous. These results, says Leudet, correspond closely to the observation which has heretofore been made, that the effect of contagion is more often exerted from the husband to the wife, than from the wife to the husband. Many other facts of the same kind have been reported, but we need not occupy time and space with them, since they conduct us to the same conclusion. Thus it happens that experimental study unites with clinical experience in rendering the existence of a contagious *materies morbi* in a high degree probable.

The specific infective quality of tubercle being thus rendered probable, it remains to indicate in what way the human race may be rid of a communicable scourge so destructive in its character. This is the subject of a paper by Prof. Corradi, of Pavia, read before the International Congress of Hygiene, assembled at Geneva in September of this year. He proposes to prevent the cohabitation of the phthisical; to abstain from food derived from phthisical sources, including milk; to avoid the use of vaccinia from phthisical heifers and infants, and to institute special hospitals for the isolation and treatment of phthisical cases.

The most superficial consideration of these prophylactic measures to prevent the extension of tuberculosis, must convince any inhabitant of a free country that they are impracticable. In those countries possessed of a paternal government, in which all the transactions of life are minutely regulated, it may be possible to prevent the contact of phthisical subjects; but surely, in this country, such absolute hygienic regulations, are entirely inapplicable. With us, there is no other dependence for the extinction of tuberculosis, than the law of evolution. Relying on the operation of natural laws, and recognizing the survival of the fittest as the great fact of development, we may await the progress of natural forces since human agency cannot be successfully applied to the amelioration of our condition—to the relief of the human race from this odious scourge.

Whilst we may not invoke a sufficient legislation to prevent the spread of phthisis, we may, by precept and example, induce the population of our time from entering into unscientific, unhygienic relations which may result in lasting injury to the human race. The only comfort which any humanitarian

can extract from the present complicated situation is that by the laws of evolution those families must become extinct whose ancestors were the subjects of constitutional diseases by inheritance.

THE LIMITS OF MEDICAL ETHICS.

"License they mean when they cry liberty."—MILTON.

IN the October number of the *New York Medical Journal* Dr. C. R. Agnew, of the committee that framed the new Code, under the above caption, and with a pleasing quotation from Addison as a subheading, to the effect that "Where liberty is gone, life grows insipid," etc., makes an attack upon what he terms the "sumptuary, proscriptive, and trades-union laws and regulations" of our profession; or, in other words, upon its Code of Ethics.

It is well that in this extraordinary production the author has included a little autobiography, as surely no one would on *a priori* grounds have attributed his article to a teacher of twenty-five years' standing, a trustee of a university, an ex-Surgeon-General of the State of New York, and a "thoroughly conservative, old-school doctor;" by all of which titles he describes himself. Neither, we may add, would it have been suspected that he was one of the orginal corporators of the Society for the Suppression of Vice.

Of course the old questions are considered, but no new light— certainly no true light—is thrown on them. Indeed, to the average mind, they would seem to be somewhat obscured by irrelevant simile and illogical argument. How, for instance, does it affect the generally received belief that a consultation between a regular physician and a quack lowers the former, strengthens the latter, does not benefit the patient, and is positively injurious to the community by encouraging charlatanry, to ask what good could come from a law forbidding engineers or astronomers to consult with mechanical or mathmatical heretics? If advocates of impossible motors or believers in the motion of the sun professed to apply their views to the healing of disease, or to be governed by them in accepting the responsibility of human life, there would be every reason for sternly and rigidly discountenancing them. Until they do that there is not even a distant resemblance between the cases.

It hardly solves the entire question as to the uselessness or harmfulness of consultations with charlatans to say that "it is for the scientific and conscientious consultant to compose all differences of diagnosis and treatment in the interests of the sufferer." It sounds well, but is somewhat vague. After careful study we confess to not knowing exactly what it means, unless an astounding proposition in another part of the article be taken as explanatory. It is there stated that when a patient in the hands of an "ignorant pretender, under whatever trade-mark, calls in consultation a competent practitioner," the latter may, under the new Code, respond to his call. If then, after "a fair discussion of the case"!!! the sick person does not dismiss the quack and retain the competent practitioner, the latter may consider himself relieved of responsibility, although he still pockets the fee. This is possibly the "composing" process above alluded to, but one in which surely no gentleman would care to be concerned. More particulars are evidently needed, especially as to the "fair discussion" which is to determine the further attendance on the patient. Is the latter to hear both arguments and decide judicially, as the final arbiter, or is he to be interrogated at the lancet-point and made to respond under penalty of being deserted by both parties? "Under which king, Bezonian? Speak, or die!" Or can it be that the Ignorant Pretender is to be overcome by the combined power of science and conscience, and is to abdicate?

The advocates of the new Code seem to be under the impression that it is an argument in favor of abolishing the old Code to say that the evils which it is intended to suppress are of considerable magnitude under its sway, but the fallacy of this position is self-evident. The same line of argument would lead to the cessation of vaccination on account of an epidemic of smallpox, or the abolition of quarantine because yellow fever occasionally made its appearance. They return to the old proposition in favor of leaving all ethical questions to the decision of the individual, and ask if the latter is not able morally to decide between right and wrong, to say whom he will or will not meet, "how is the moral capacity acquired to make the decision wisely by the aggregation of a number of individuals, every one of whom is supposed to be individually incapable?" There is a flaw here, however, in the major premise. No one supposes, or, so far as we know, has ever asserted until now, that any such incapacity for proper discrimination existed in the profession. Such arguments rest on the grossly unwarranted assumption that ethical rules are made for the government only of persons unfit to govern themselves. We have already had occasion to point out that ethics and morality are practically synonymous. Is it, or does any sane person suppose it to be, an argument against the general canons of morality that they are framed into laws for the control and the welfare of society by persons, some of whom *do*, and any of whom *may*, transgress them?

We have no space to devote to refutation of such puerilities, but would like in concluding to call attention to two statements which hardly seem consistent with the self-assumed character of a "thoroughly conservative, old-school doctor."

Dr. Agnew says distinctly and without qualification that whereas, under the new Code the primary object of the physician is to be the good of the sick, "under the old Code the primary object came to be the 'dignity of the profession,' and an inquisitorial scrutiny of one's professional rivals." In other words, we are just now to begin, under the guidance of the new Code, of course, to try to help suffering humanity, to alleviate distress, and to combat disease, after untold years of misbehavior in which these objects were neglected or subordinated to petty and personal jealousies. Imagine the effect of this outrageously false statement upon the lay mind—coming as it does from so prominent a source.

Finally, and we mention it as an illustration of the logical and inevitable lowering of professional dignity involved in an acceptance of the new Code, he digresses to approve of Senator Cameron's joint resolution throwing open the governmental service to all so-called "doctors;" stating that the resolution of that dignitary "does not provide for the recognition of 'irregulars,' but of men with legal diplomas." That is to say, he does not consider any herbalist, clairvoyant, eclectic, mesmerist, or homœopath an "irregular" if he be provided with a recognized certificate of his right to practice. This is, of course, equivalent to abolishing altogether the term which has come to mean a practitioner of medicine who displays his ignorance or dishonesty by adopting some special insignia or trade-mark, or who transgresses in some other manner the laws of professional honor and decency. The word cannot, as we have said, be consistently employed by the supporters of the new Code, and Dr. Agnew shows his appreciation of that fact by repudiating it as applied to the subjects of Mr. Cameron's resolution. We prefer, for ourselves, to retain it as well expressing the broad distinction between respectable physicians and the class above described. Fortunately, there is no danger that either the word or the difference which it indicates will be forgotten by the profession at large, however they may be ignored by the advocates of the new Code.

CAFFEINE IN CARDIAC AFFECTIONS.

NOTWITHSTANDING the remarkable value of digitalis in the treatment of various cardiac diseases, there are conditions in which it may be indicated, but yet is not available owing to peculiarities of its action. The discovery of other remedies, having similar effects, but free from its objectionable features, becomes, then, very desirable. Amongst the new contributions to our resources in cardiac therapeutics, are nitro-glycerine and convallaria. Caffeine which has long been known as a cardiac stimulant and diuretic, has begun to assume new importance since its special powers as a cardiac remedy come to be better understood. In a recent number of the *Bull. Gén. de Thérap.*, Dr. Heuchard has a paper in which caffeine is contrasted with digitalis, and the applications of the former are mapped out with precision. It may be useful to some of our readers, to learn the capabilities of caffeine as a cardiac remedy, and to compare the observations of Heuchard with those of other observers, notably of Steward.

As is the case, so generally, the action of caffeine in small and large doses varies, and the secondary is different from the primary action. In the first phase of its effects, or administered in small doses, it stimulates the action of the heart and raises the arterial tension. When considerable doses are given the stimulant effect is of brief duration, and is soon followed by a fall in the number of the heart-beats, and in the tension of the arterial system, which is the second phase of its action. Caffeine augments the flow of urine. Its action is brief, owing to the rapidity with which it is eliminated, and it has no toxic effect properly speaking.

In some cases the diuretic action of caffeine is preferable to that of digitalis; although not so considerable, the diuresis occurs more promptly, and it may, therefore, be employed when a prompt effect is essential. Caffeine has the advantage that it is by no means so irritating to the stomach, and can be used in such diseases, as cirrhosis, for example, when digitalis could not be borne. In cases of cardiac diseases, where the muscular wall of the heart is affected with fatty degeneration, and in which digitalis is so dangerous, caffeine may be used without risk and often with decided benefit. Of course, it cannot take the place of digitalis in the valvular affections with dropsy, in which this remedy is so efficient.

Dr. Heuchard maintains that caffeine must be given in large doses, if the desired effects are to be procured. Beginning with four to eight grains, he rapidly increases the dose to ten, to sixteen, even up to thirty grains three or four times a day to maintain a constant effect.

DEATH-CERTIFICATES AND BURIAL IN CASES OF STILLBIRTH.

A CASE which has excited some attention from the lay-press has recently occurred in Philadelphia, and brings up one or two interesting points in relation to the giving of death-certificates. The facts are briefly as follows: Dr. Bell, a physician to a poor-district, was called on a Monday afternoon to visit a woman in labor; having at the time other pressing cases of the same sort, he placed her in charge of a medical student belonging to a class who were taking instruction in practical ob-

stetrics. This gentleman saw the patient at four o'clock, remained with her until five, and came again at about seven, to find that in the interval a dead child had been born. He severed it from the placenta, placed it in a box, and directed the father to bury it in the yard. The following day the parents asked him for a death-certificate, and were referred to Dr. Bell, who, not having seen the student, declined to give it, and sent them to Dr. Elliott Richardson, the instructor in charge of the class to which the student belonged, who immediately wrote, asking for particulars, but heard nothing further from any person. Dr. Bell and he each supposed that the other had attended to the matter, no certificate was given, and finally, a partially correct version of the affair was published in one of the daily papers.

We give these details partly to place the facts before the profession, who are always interested in such matters, and partly to call attention to the proper procedure in such cases.

In many parts of our country, and in some of the rural districts in this State, death-certificates in such cases are not required by law or custom, and stillborn children or the products of premature labors are often disposed of as was suggested in this instance.

In Philadelphia, such cases come under the general laws relating to births and burials, no mention of stillbirths being made in the city ordinances, as far as we can discover. The custom is, we believe, to dispose of the product of conception in any decent and inoffensive manner and without formality if it has not reached an age when it could by any possibility have survived. After the period of viability, which may be said to be from five to six months, it, of course, becomes important to know whether the child was born alive or dead, and a certificate from the attending physician or, in case of his neglect or refusal to attend to it, from the health officer is required. Suspicious circumstances properly sworn to would very properly throw any case into the hands of the coroner. In the instance we have just mentioned the accidental character of the complication was so evident that the case was promptly dismissed by the coroner's jury.

RESECTION OF THE PYLORUS.

THE surgeon of to-day should not be accused of timidity or of too great conservatism. It is scarcely three years since the first resection of the pylorus was done, and yet, in spite of the comparative rarity of cases suitable and willing for such an operation, CECCHERELLI has collected in *Lo Sperimentale* for August, 23 cases, to which at least Hahn's second case must be added. Of the 24, nine recovered from the operation. What the ultimate results were is quite another question. Billroth leads in number though not in time with four cases; Czerny, Rydygier, and Hahn have each done it twice; as we said lately, however, in the matter of extirpation of the larynx for cancer, so as to resection of the pylorus, we do not believe that it will ever take its place as a recognized and justifiable surgical procedure, save in very exceptionable conditions. Until we can hope for a permanent cure of the carcinoma, the operation is so painful and so dangerous that a conscientious surgeon can scarcely recommend it. With resection of the intestine it is quite different, since the diseases which call for its resection are so entirely different. A brilliant example of this is seen in the case of double and successful resection of the intestine reported by Rydygier in the *Berliner klinische Wochenschrift* for Sept. 18th last.

THE recent terrible accident in Fairmount Park, by which nearly a score of persons were killed and wounded by the premature explosion of fireworks, has called attention anew to the dangers of such amusements. Of course no possible pleasure can weigh against such a dreadful calamity. The Mayor of Philadelphia, we see, has declared that no such exhibitions shall be allowed hereafter. If fireworks involve such dangers, they must be given up. For places fortunately provided with a river, as Philadelphia is in the Schuylkill, we have a suggestion which we think will allow of the pleasure and yet prevent the danger. Moor some canal-boats in the middle of the river and plank them over as a platform for the fireworks. Then police the river by a few tug-boats to keep spectators at a proper distance. The fireworks can be better seen, since neither trees, hills, nor other obstacles will be in the way; they can be seen to advantage by a greater number of people, for those on both sides of the river can see them; and none but the few engaged in displaying them will be exposed to any danger; and the caution born of experience will enable them to escape.

So many patients use the telegraph and so many doctors make appointments by telegraph that its reliability and speed become a matter of no little moment. Of late, however, it has become most unreliable and vexatious. Again and again have we found two hours to elapse between the dispatch and the reception of a city message; and as to messages to the suburbs, it is not uncommon for a doctor to *drive* out there and find that he has arrived long before his message. The actual loss from failures to make and keep appointments is considerable, and the evil should be remedied. The best way to do so is to make official complaint to the company in every

instance and to demand at least the return of the cost of the message. We have known this to be done in several instances, and its frequent recurrence will cause reform. Corporations keep both their consciences and their cash in their pockets.

Can a person be tried as an abortionist in consequence of an attempt to produce an abortion on a woman who was not even pregnant? Such is a question lately mooted in Chicago. The girl died of metro-peritonitis as a result of the manipulation; but the autopsy showed that the supposed pregnancy never existed.

REVIEWS.

A System of Surgery, Pathological, Diagnostic, Therapeutic, and Operative. By Samuel D. Gross, M.D., LL.D. Cantab, D.C.L. Oxon, Emeritus Professor of Surgery in the Jefferson Medical College. Illustrated by upwards of 1600 engravings. Sixth edition, thoroughly revised and greatly improved. In two volumes. 8vo. pp. xxxii. 1194, and xxxii. 1174. Philadelphia: H. C. Lea's Son & Co., 1882.

Who does not know "Gross's Surgery?" And who that knows it, does not trust and consult it? And who that knows its author, does not love and revere him?

This book, like all other human work, has of course its defects and its errors; but nevertheless it is monumental. A sixth edition so thoroughly revised, and so fully brought up to date, is both a delight and a surprise. Its author is a man well advanced in years, and has been a distinguished teacher for over half a century. Yet just as he lays down the crown of the teacher he takes up anew the sceptre of the author, and labors day and night in perfecting a work already great, which now fully reflects the wonderful growth of surgical science in the decade since its last revision.

The new edition is a surprise not only by the amount of labor involved in its preparation, but also by the readiness with which its learned author has accepted new views. The conservatism of age has kept him from attractive but unproven theories, but it has not hindered his change of opinion with the advance of knowledge or the welcome due to the later views in pathology and in therapeutics. Moreover, he has had the wisdom to recognize the value of specialism in medicine, and to avail himself of the pens of several able assistants. Thus Cohen has revised the chapter on the respiratory organs, Harlan that on the eye, Burnett that on the ear, in addition to the aid in other parts from Thomson, Seguin, Battey, L. H. Sayre, and Dunglison, while the book shows on many a page the skilful and able hand of Prof. Samuel W. Gross, the worthy successor of his father in the professorial chair at Jefferson Medical College.

The work is worthy of its distinguished author, and is a monument to his learning, his industry, and his skill. Long may it be his privilege to reap its fruits and enjoy the honor of his labor.

The Physician's Visiting List for 1883. Philadelphia: P. Blakiston, Son & Co.

For over thirty years, this extremely useful book has been an annual visitor. Steadily, too, it has grown better, until now it can scarcely be improved upon. Two sizes are made, for twenty-five and fifty patients respectively. Besides the daily visiting list, there are an almanac, a description of Marshall Hall's ready method in asphyxia, tables of poisons and their antidotes, weights and measures—including the metric—a posological table, with blanks for the addresses of nurses, obstetric engagements, accounts, etc. We welcome its familiar face, and only suggest that, since Silvester's method of resuscitation in asphyxia is better than Hall's, as we showed in our issue of August 12, it should replace the latter.

A Treatise on the Physiological and Therapeutical Action of the Sulphate of Quinine. By Otis Frederick Manson, M.D., Professor of Physiology and Pathology in the Medical College of Virginia. Pp. 64. Philadelphia: J. B. Lippincott & Co., 1882.

We are quite unable to discern the motive for the publication of this monograph. The modern researches which have thrown light on the action of quinia, are simply ignored. The writer seems to have no acquaintance with the literature of a more recent date than the treatise of Giacomini on Materia Medica and the monograph of Briquet on quinia and its preparations. It seems idle to be engaged in the vamping-up of old works, when modern works, which contribute something towards the solution of the problem, are right at our hand. So far as he has gone, well enough; but Dr. Manson should have withheld this effort from publication until he had extended his researches into the contributions of modern therapeutists. If he had done so, his treatise would have contained matters of the greatest moment to the profession. As it stands, we do not see that the real ability of the author has found a proper scope for development.

The Vest-pocket Anatomist (founded upon "Gray"). By C. Henri Leonard, A.M., M.D. 12mo. pp. 82. Detroit: 1882.

Though "founded on 'Gray,'" as upon a rock, we trust that this book may suffer the destruction of the house of unstable foundation. So far as we can see, there is but one good thing about it: the author—no, we mean the compiler—justifies his A.M. by a correct Latinity, even down to anconéus, corrugátor, and masséter, though he comes to grief on the "nervus pudica."

It is from beginning to end simply an advertising affair. The compiler gives his titles in full, from Professor of this and that, down to his membership in a no doubt justly celebrated County Medical Society, but whose fame, we regret to say, never before had reached our ears. What terrible titles then must be hidden under the final "etc!" The preface tells of the "surprise and pardonable pride of the author"—for such by courtesy he calls himself—in the rapid sale of the book. On the opposite page are advertised five other "works"—Heaven save the mark!—by the same "author;" namely, one on the Hair, a Reference and Dose Book, a Manual of Bandaging, a Day Book, and a Ledger! At the end of the book, the same now familiar friends appear, together with Dr. Leonard's vaginal speculum and Dr. Leonard's utero-metric sound. Of course, being a professor of gynecology, he must invent a new sound and a new speculum. But the crowning glory is still wanting. Let him invent—and advertise—a new *forceps*, by C. Henri Leonard, A.M., M.D. The world waits for it.

The book is a worthless rehash of the simplest facts of anatomy—one of that miserable class of books for cramming, that we only notice to condemn, along with the advertising methods of its "author."

SOCIETY PROCEEDINGS.

THE AMERICAN ACADEMY OF MEDICINE.

Seventh Annual Session, held in Philadelphia, October 26 and 27, 1882.

(Specially reported for THE MEDICAL NEWS.)

THE seventh annual meeting of the American Academy of Medicine was held in Philadelphia, at the hall of the College of Physicians, on Thursday and Friday, October 26 and 27, 1882, DR. TRAILL GREEN, of Easton, Pennsylvania, President, in the chair.

After the reading of the minutes, the names of about fifty applicants for membership were read by the Secretary, as having been approved by the Council. All of these gentlemen were then elected as Fellows of the Academy. It may be stated that the Fellows are selected from those only who have received the degree of A.B. or A.M. in regular course, in addition to that of M.D., and that the chief purpose of the Academy is an improvement in the preliminary education of those who are about to enter upon the study of medicine.

An amendment to the constitution, proposed at the last meeting, limiting the number of vice-presidents to two, instead of four, was rejected.

The Secretary read a short paper by Dr. ELISHA HARRIS, of Albany, New York, on

THE PUBLIC HEALTH SERVICE IN ITS RELATIONS TO THOROUGH PREPARATION OF THE PHYSICIAN.

He urged that the experience of numerous communities is continually demonstrating that the majority of practising physicians have so failed to prepare and outfit themselves in the natural sciences, in habits of accurate and studious observations and medical logic, and in mastering the stores of knowledge, that they are not adequately educated for the highest duties of public sanitary service. The time and cost of the disciplinary course of study which the writer considered so desirable, are never a waste, and the acquisition of science and of the essential habits of scientific study will become the wealth which the sanitary counsellor and health officers most need.

The deaths of three Fellows of the Academy were alluded to by Dr. C. C. Bombaugh, of Baltimore, Md., after which the Secretary read a semi-biographical minute of the professional services of Drs. H. Lenox Hodge, of Philadelphia, James M. Shearer, of Dillsburg, Pa., and William H. Allen, of Philadelphia, the deceased fellows referred to.

DR. BENJAMIN LEE, of Philadelphia, then read a paper on

THE ADVANTAGES OF A LIBERAL EDUCATION PRELIMINARY TO THE STUDY OF MEDICINE, AS ILLUSTRATED IN THE EARLY HISTORY OF MEDICINE IN THE COMMONWEALTH OF PENNSYLVANIA.

The objects of the paper were, first, to claim for Pennsylvania that meed of praise which is her due as the mother of medical science in this country; and, secondly, to show that she owes this proud position in history to the fact that so many of her early physicians were men of liberal education and elegant scholarship, the majority of those whose names have come down to us as worthy of remembrance having taken the degree of Artium Baccalaureus before they entered upon the study of their profession. The physicians of Philadelphia, in the middle of the last century, were not men of limited education or scanty intelligence. On the contrary, there are few of us at the present day who would care to institute a comparison between the more prominent of them and ourselves, as to classical culture, general knowledge, elegance and polish of manner, habits of thought and observation, and in certain branches even as to professional attainments. The paper was full of interesting historical and personal reminiscences of the medical men who flourished in the days when the little city on the banks of the Delaware had only fifteen or twenty thousand inhabitants. It was true then, it is true now, said the writer, that while the physician who has enjoyed no early advantages in the way of a finished education, and has taken no pains to remedy this deficiency later in life, may be a successful physician and acquire a lucrative practice; he rarely becomes a leader of medical opinion, a founder of schools, a reformer of error, an ornament to his profession.

DR. H. O. MARCY, of Boston, Massachusetts, then read a paper on the

ANTISEPTIC TREATMENT OF OPERATION WOUNDS,

in which he discussed, in an exhaustive manner, the general principles involved. After a general review of the antiseptics used at the present day, he gave a statement of numerous experiments carefully made by himself, with carbolic acid, chloride of zinc, thymol, boracic acid, salicylic acid, etc. He found that carbolic acid still stands at the head of the list of antiseptics. Next comes thymol; but boracic acid he found much inferior to the rest in antiseptic virtues.

DR. LEWIS H. STEINER, of Frederick City, Maryland, read

A REPLY TO A RECENT CRITICISM OF A COLLEGE PROFESSOR UPON THE OBJECTS OF THE ACADEMY,

in which the latter had contended that a college education rather unfits a person for the practice of medicine. The writer of the reply showed conclusively that such was not the case, and urged in the most strenuous manner the great need of good preliminary education to those entering upon the study and practice of medicine.

DR. GEORGE M. BEARD, of New York, then read in abstract a very elaborate paper on

THE MEDICAL PROFESSION, AND MEDICAL EDUCATION IN EUROPE.

The general conclusions reached by the writer, after considerable personal study abroad, may be formulated in three propositions: 1st. The best system of education in Europe, including both preliminary and medical, is found in Germany. The German physicians are the best educated in the world, both in general and special training. 2d. Next to Germany comes France, where as in Germany it is impossible to get a medical degree without a more or less thorough preliminary education. 3d. In Great Britain less preliminary education is required for medical students than in any other of the great nations.

The special defects in the English system are, in addition to the deficient preliminary education, 1st. Too little instruction; 2d. Too much examination. It is estimated that only a small per cent. of the English physicians are graduates of Oxford and Cambridge. If a student must economize in time or means, let it be in the professional and not in the academical training; lengthened terms of medical study will not alone very greatly raise the character of our profession. No amount of medical education can make up for deficient general education, and no examinations, however severe, can take the place of instruction. Medical books, especially recent cyclopedias and monographs that are not needed by medical students, have a much smaller sale and are less generally read than in America. Ziemssen's cyclopedia, which in this country sold by thousands, was purchased in England only by a few hundreds. German and French mono-

graphs have comparatively a limited circulation in England as compared with this. Outside of a small circle of German-taught experts the medical literature and the medical practice of England is from five to fifteen years behind Germany and America.

The *Staats examen*, or State examination, is one of the glories of Germany; it is by a central and independent body whose members are not members of the faculties through whom the candidates acquire their education; and whose chief temptation is to be just.

The Germans are thinkers, philosophers, men of abstract ideas with inherited genius for theory and for language. In Germany nothing counts but originality; a man must say something or do something different from what has been said or done before. Germany is a great medical centre, because it is a great thought centre.

The defects of Germany are mainly on the side of practical application of science and philosophy to daily wants in medicine, the special great defect is in the treatment of disease; the German are non-therapeutists. The social status of the profession in Europe is a reflex and reward of education and character. The profession as a profession has slight honor; the position of its individual members comes from individual characters despite the calling.

The practical applications in this country are these: Encourage young men about to study medicine to acquire university education in the very best of our universities.

Encourage young men to study and travel in Germany.

Encourage young men to do original creative pioneering, both in medical philosophy and medical experiment.

Within two decades America has pushed forward largely under German inspiration and encouragement at least a century.

EVENING SESSION.

The Academy reassembled in the evening, to hear the

ADDRESS OF THE PRESIDENT, DR. TRAILL GREEN.

He alluded to the progress ef sentiment in favor of an improved preliminary education since the foundation of the Academy, and to the views of many honored teachers in the profession, whose experience in the schools, as well as in private practice, qualified them to judge of the wants of those who were asking admission to the profession, such as Drs. John W. Francis, N. Chapman, Alexander Sterns, Jacob Bigelow, Oliver Wendell Holmes, N. S. Davis, J. R. Wood. W. K. Bowling, S. D. Gross, and many others. From year to year the American Academy of Medicine has made constant advances, and distinguished practitioners and eminent teachers continue to enroll themselves in the annually increasing list of the Fellows. He cited, as a point accomplished through the influence of the Academy, the law of the State Medical Society of Pennsylvania, passed in 1878, demanding that students of its members should be examined by boards of medical examiners, appointed by county medical societies, as to educational qualifications, before entering upon their medical studies; and in 1880 the Society enforced the law by refusing representation from county societies which did not comply with the law. Prof. Tyson's address, delivered in 1882, he quoted, in which he urges that "the finished physician shall not only be thoroughly trained in all that pertains to our profession, but he shall also possess a university education or its equivalent." In 1876, the year of the organization of the Academy, Harvard was the only school in this country which required a preliminary examination of intending medical students; now there are thirteen colleges which require the diploma of a literary institution or a preliminary examination, and three schools require a preliminary examination, The speaker thought that this exhibited great progress in six years. He thought that the colleges which demand such examination will have public sentiment to sustain them. May it be our purpose, he said in conclusion, to so impress the minds of young men who are looking to the medical profession as the field of their labor that their experience may be that of cultured scholars and skilful physicians, whose lives may be useful and adorned by the liberal culture to which we invite them.

SECOND DAY, OCTOBER 27TH.

The Academy met at 10 o'clock, and, after hearing the Treasurer's report, the report of the Nominating Committee, appointed on the previous day, was presented, and the following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—DR. H. O. MARCY, of Boston, Massachusetts.

Vice-Presidents.—DRS. GEORGE M. BEARD, of New York; WM. ELMER, of Bridgeton, New Jersey; CORNELIUS R. AGNEW, of New York; and THOMAS M. DRYSDALE, of Philadelphia.

Secretary and Treasurer.—DR. RICHARD J. DUNGLISON, of Philadelphia.

Assistant Secretary.—DR. CHAS. MCINTIRE, JR., of Easton, Pennsylvania.

The next meeting is to be held in New York, in September, 1883.

After the election of several additional Fellows, the Secretary read letters received from the attending and consulting surgeons of the late President Garfield, received in response to the resolutions of sympathy and respect passed at the last annual meeting of the Academy.

On motion of DR. STEINER, the Secretary was authorized to make arrangements hereafter for a collation at each meeting, after the delivery of the annual address of the President, for such of the Fellows as may notify him of their desire to join in the same, the expense *per capita* not to exceed two dollars.

DRS. HENRY FRAZER CAMPBELL, of Augusta, Georgia, and AUSTIN FLINT, SR., were then elected *honorary members* of the Academy.

The Secretary read a paper by DR. NATHAN ALLEN, of Lowell, Massachusetts, upon

THE INFLUENCE OF MEDICAL MEN,

in which he discussed the various channels of usefulness in which the educated physician could make himself useful in improving the moral, physical, and sanitary conditions of the community.

Dr. Dunglison, who had been appointed in 1880, with Dr. Marcy, of Boston, a committee to report on

THE LAWS OF MEDICAL PRACTICE IN THE UNITED STATES AND CANADA,

Presented the Annual Report, exhibiting the progress which had been made during the last twelve months in this form of legislation, showing the modifications in some States, the defects in others, and the general advance made in this direction in the various States of the Union since their previous report. The Committee had obtained official copies of almost all the Acts of medical interest now in operation in the various States, and in the Dominion. So far as their knowledge extended, laws of many and different degrees of force and efficiency are now existent in twenty-two States, and two territories, and in all the Provinces of Canada, having for their object the regulation of the practice of medicine. The States and Territories referred to are

New Hampshire, Connecticut, New York, New Jersey, Pennsylvania, Virginia, West Virginia, North Carolina, South Carolina, Georgia, Alabama, Mississippi, Louisiana, Texas, Arkansas, Illinois, Missouri, Colorado, Wisconsin, Kentucky, Nebraska, California, and Washington and Wyoming Territories.

DR. MCINTIRE then read an excellent paper on

THE RELATIONS OF THE ACADEMY TO THE PROFESSION.

The writer first inquired into the exact condition of the medical profession as at present constituted, having obtained data for the classification of physicians upon an educational basis, from statistics collected from county and other medical societies in Pennsylvania and New Jersey, from a large number of college catalogues, etc., the object of the writer being to show that a very small percentage of college graduates become physicians, and that a very large majority of medical men have never received any college training. The paper, which was elaborate and carefully written, teemed with interesting statistics, the publication of which would be essential to an intelligent appreciation of the merits of the paper. The writer dwelt in conclusion upon the high mission of the Academy, and suggested means by which its usefulness might be extended.

After a vote of thanks to the College of Physicians for the use of their Hall, and to the fellows resident in Philadelphia for a collation tendered the visiting fellows at the Colonnade Hotel, on the previous evening, the President-elect, Dr. H. O. Marcy, was inducted into office. After eloquent remarks by the latter, and by the retiring President, and the appointment of Dr. Benjamin Lee, of Philadelphia, and Dr. L. D. Bulkley, of New York, as additional members of Council, the Academy adjourned.

CORRESPONDENCE.

A FEW WORDS ON THE ESTABLISHMENT OF VETERINARY SCHOOLS IN THE UNITED STATES.

To the Editor of THE MEDICAL NEWS.

SIR: The caustic and true remarks, in your editorial of the issue of September 30, under the heading of "The Medical School Scandal," so fully coincide with those I have repeatedly published with reference to the establishment of veterinary schools in this country, that I feel emboldened to trespass upon your indulgence with a few remarks.

The general public, and I am very sorry to say, also, many members of the medical profession as well, scarcely realize, to its full extent, the value of veterinary science to a country, especially from the economical and hygienic standpoints. The veterinarian is generally looked upon as part of the adjuncts of the stable or kennel; and any attempt on his part to show he has duties of a more elevated character are looked upon as the dreams of a visionary enthusiast. These *dreamers*, however, find sufficient evidence to support their assertions in the testimony which is given by the gradual decrease of the losses occasioned by annual pests on the continent of Europe in comparison with those of the last and previous centuries, when gods or devils were supposed to instigate them as tortures for humanity, who fled to the impotent priests of the day for relief, instead of to scientific study of the causes and nature of these devastations.

But aside from the study and treatment of animal disease *per se*, the educated veterinarian is destined to play a still more important part in the world's progress, a sphere in which he stands, or may stand, in every way on a plane with the most advanced mediciners; this field is that of public hygiene, and the veterinarian's special branch is, *the relation of animal diseases, or the products from diseased animals, to the health of humanity*. One need but allude here to market and slaughter-house inspection, to the contagious diseases transmissible to man; to trichinosis, tuberculosis, and last, but not least, to the inspection of dairy stock, by which the consumer may be assured that the cow giving the milk is healthy, as well as that the milk is not adulterated after being taken from the cow. Our milk inspection, as at present carried out, begins at the wrong end of the route; we examine the water at the faucets of delivery, but entirely neglect the fountains, or sources, from whence it springs. That the time has come when certain authorities, communities, or individuals, are beginning to appreciate the demand for a greater number of veterinarians is made evident by the success of certain private (speculative) institutions for the education of students, and that several of our universities are taking steps in that direction.

Your remarks, above alluded to, bear especial relation to the case in point, and should by no means be lightly passed over by those entering upon this path of education. It will not be over fifty, and perhaps not twenty-five years, before this country will be as completely overrun with irresponsible, speculative veterinary schools, displaying the disgusting and degrading phenomena of hunts after students, cheap diplomas, general rivalry, etc., which now exists, and so disgraces what may be called the medical institutions of the United States, though of course there are, and ever will be, exceptions to this rule. One thing must not be forgotten, the demands of the public for veterinarians will never be as great as for mediciners.

From what has been done so far, and is at present contemplated, it would seem as if we were bound to utterly ignore the teachings which may be drawn from countries where veterinary schools have existed for a century or more.

If we follow any example, it is that of England, which is only to be at once condemned, the schools being private affairs, utterly without responsibility, until the profession took its protection into its own hands by the formation of the Royal College of Veterinary Surgeons, which is acknowledged by the Government (only within a few years), and now constitutes the examining and diploma-granting body. Even this we can scarcely ever expect to arrive at in this country.

With reference to these British schools it should never be forgotten, that neither of them have ever produced any scientific contributions to veterinary literature, and that all that can be said of them is that they are and have been successful in producing good routine practitioners.

The case is far different with the continental schools: the work of their teachers forming the foundation upon which our veterinary literature at present stands. In this regard one need but mention the names of Gerlach, Bouley, Channeux, Toussaint, Erculasic, and others; men who have not been without their contributions of value to general medicine.

The English schools are, in reality, nothing more or less than speculative affairs, the benefits going to the teachers and the subscribers, who, for a certain sum per year can have the benefits of the school hospital. There is no very good feeling existing between the profession in the cities where these schools are, especially London, and the faculty, the schools frequently doing a "cutting" business with regard to fees.

Again we see it proposed to have one or two technical teachers attached to the faculty of our medical schools, *vide* Harvard. Fully aware that this is but a beginning,

we nevertheless feel that it is a mistaken one, not only with reference to Harvard, but more to the advancement of the profession. It is absolutely impossible for the teachers of human medicine to properly adapt themselves to veterinary medicine; and again, it can only lead to production of routiners in medicine. Virchow would speak of such teachers as "Mädchen für alle," servants for general housework. The question is what do we want to produce, routine practitioners or scientifically educated men?

So far as the country goes, so far as any appreciation of medical science *per se*, either for the young mediciner or veterinarian, I mean ability for original research as understood in Europe, any American might as well blow his brains out at once and throw his money into the fire; there is at present no place for him in the United States, unless he has money enough to establish a private laboratory, work for his own pleasure, and publish his work in Europe. His profession would pat him on the back and speak of him as a good fellow, but a fool; "better make money," the ultimum of American success. The people in general would call in the first quack in preference, in consequence of his "great practical experience" (in gulling people out of their money).

Unfortunately my ambition for both human and veterinary medicine is on a higher plane. What we want is more of the true scientific spirit in our schools and permeating the profession. If not in the faculty, it will never be in the profession, and it will never be in the profession with the schools as they are. The chartering of private, utterly irresponsible schools for medical education in any branch cannot be too strongly condemned. Even should the different States establish State schools, funded and controlled by their respective authorities, we should be so overflowed with practitioners, as human medicine now is, and there would be as great an inequality in the quantity and quality of education given or demanded of graduates as now exists in human medicine, and a graduate's diploma as worthless until we knew from which school he came.

If it were conducive to the best interests of a country to have one or two technical teachers attached to medical schools, for the advancement of veterinary science, we should not see the great powers of Europe supporting entirely separate institutions at great expense. The Berlin schools cost more than $20,000 per year above receipts, with large faculties. Berlin has 13 professors and a large number of assistants, and is erecting institutes for the study of special branches; the new pathological institute at Berlin is to cost $50,000; at least such is the appropriation. It is from the work done at these schools that we have learned how to control animal pests, and the nature of most of the diseases of our animals.

When we come to ask how is it that such work has only been done at continental schools? we find the simple answer, that they are government schools, supported and controlled by their respective governments. We find, unquestionably, that most of the students graduated simply became practitioners, but still the scientific spirit is instilled into them, and if real genius for original work comes in but one out of a thousand, still that one finds support and encouragement from his colleagues, and becomes a useful servant to the State.

Notwithstanding the present rottenness of our Government and the manifold injurious influence of American politics, it would be better for the country could this new movement die while in its embryo condition, and be substituted by one or two large schools supported by the government. We should then have one standard of education and the rivalry of schools, which will never be healthy, scientific, but for students, would cease, and we should not have what now exists in human medicine in our different cities, antagonistic cliques, or societies, composed of the graduates of different schools, each having more or less bitterness towards the other. This condition even exists among veterinarians to-day. If the medical profession is really alive to its own future progress, it will use its influence to keep our new branch of study from following its own bad example.

Respectfully, yours,

F. S. BILLINGS.

BOSTON, October 28, 1882.

A CASE OF RUPTURE OF THE LONG HEAD OF THE BICEPS.

To the Editor of THE MEDICAL NEWS.

SIR: Early in July a German æt. 57, of strong frame and sanguine temperament, a photographer by trade, came to me complaining of great pain and soreness in the region of the shoulder. An examination revealed the following deformity. The right biceps muscle was displaced downward and inward toward the body. There was a marked depression on the outside of the muscle. On flexing the forearm on the arm, the muscle elongated itself somewhat and drew further inward. The history of the case showed that whilst he was lifting a stove and at the same time drawing it toward him, he felt something give way in his arm and heard a distinct *snap*, at the same time becoming so faint as to be obliged to sit down. As soon as he was sufficiently recovered, he came to my office, where a fracture of the long-head biceps was diagnosed and he was treated by simply placing his arm in a sling. On account of the infrequency of such accidents, I have had him photographed and reported his case.

Yours, respectfully,

CHAS. K. LADD.

TOWANDA, October 27, 1882.

"SANITARY INSPECTION OF SEA-SIDE RESORTS."

To the Editor of THE MEDICAL NEWS.

SIR: I am glad to see an editorial in your issue of October 28, on the subject indicated above. There can be no doubt of the necessity for rigid sanitary inspection of the entire shore line of New Jersey; but there is one remark your editorial discloses that is not in strict accordance with the facts. It is this, "The soil of the whole Atlantic border of the State predisposes to a bad sanitary condition," etc. While this may be true of some sections, it is certainly not applicable to that portion of the coast, a distinguished feature of which are the *Highlands of Navesink*. Taking Sea-Bright as a starting-point, and following the northern and western line of the coast, for a considerable distance, the elevation above the sea ranges as high as two hundred feet, and the soil is a rich loam, with a gravel subsoil, which is under thrifty cultivation to the water's edge. The natural surface-drainage is complete, and the soils which underlie the surface, contribute by nature the elements for successful subsoil drainage. The forests are totally devoid of the characteristic Jersey pine, which only thrives in sandy land and is seldom found on hilltops. The Shrewesbury and Navesink Rivers skirt the foot of the mountain spurs, and the lawns of the summer villas which enliven their shores are green and fertile on a natural soil, the productiveness of which is proverbial.

The Board of Health should penetrate this region also, and should be none the less inquisitive and searching in its procedures, but yet it is due to truth and fair-

ness that exception should be made to your remark, which embraces "the whole Atlantic border," by excluding the region of the Highlands, which though comparatively small, does constitute a decided exception to the general and superficial observations of the coast of the State. For years past I have visited in the summer some part of the Atlantic coast of New Jersey, and am somewhat familiar with the line from Cape May to Sandy Hook. During the last summer I spent two months in the region referred to, and during that time took special pains to inquire of physicians and others into the prevailing disorders and their causes. Also in correspondence with the Board of Health of the State, urged a strict sanitary inspection of that, as yet, comparatively new region, that I might be fortified in the conclusions to which I had arrived concerning its exceptional advantages. I have the promise of the Board, but they have been so occupied with other duties that they have not yet made the inspection. I do not believe that any new place should be patronized as a summer resort that does not first secure the approval of the State Board of Health as to its sanitary condition, and that such approval should take the form of a certificate that should be framed and posted in every hotel and at all conspicuous places within the jurisdiction. The public would then have some assurance in which they could confide. As it now is, we are subject to the caprice and ignorance of local authorities and interested parties.

In the Highland region referred to, there are already evidences of marked improvement and growth. Navesink Park, Glenoble Park, Atlantic Highlands, Hillside Park, and corporations under other names are occupying and developing this remarkable region, which for beauty of situation, splendid mountain and forest drives over good roads, and magnificent ocean and landscape views, cannot be excelled. It needs only one thing more to complete the circle of attractions, and that is the guidance and direction of the State Board of Health to outline its sanitary policy. This has been solicited, and in due time will be secured, at least so far as Glenoble Park is concerned, and I have no doubt other parties in the same region will be glad to have the Board direct their course in matters appropriate to their special function.

As to the action of the press in this connection I am satisfied it sometimes speaks without proper knowledge or investigation. Much is said about *malaria*—a term that is used in a very indeterminate sense, and I am sorry to say, by the profession, as by others. People frequently overlook the fact that sewer gas that is eliminated during their absence and permeates their closed dwellings to greet them on their return from their vacations, produces illness, which is at once attributed to a summer residence in a locality that has not been protected by suitable sanitation. The old idea, that people may live in a malarious district for several consecutive months or even years and not be affected by the malarial conditions till they remove to a more healthy climate, still clings to many people, and they thus make grave mistakes as to the causation of diseases of which they may become the victims. I venture to say that there is no more common word that is on every tongue, and that is used by everybody to account for every form of disorder than the word malaria. Indeed it is now applied as a term designating a disease—you have the malaria, as one would say you have smallpox, is a very common way of putting it, and it is certainly as unscientific as it is untrue.

As I write this page I am in receipt of a letter from a medical friend in another State, who says: "I am just out from an attack of malaria." Had he proceeded to indicate the nosological rank of his disorder I should have been gratified. He resides in a hilly and rocky part of New England, and it is possible that the form of malaria in that locality differs from that which you describe as originating in a soil that is "porous," and "so saturated with decaying filth that it is a serious source of danger." Your description is unfortunately too true to be overlooked with safety, or denied with success; but it does not apply to the whole coast of New Jersey. There are exceptions, some of which I have ventured to introduce to your readers.

I am, Sir, yours, etc., J. P.

BURLINGTON, N. J., October 30, 1882.

NEWS ITEMS.

BROOKLYN.

(*From our Special Correspondent.*)

IMPURE DRINKING WATER.—Several cases of sickness having been alleged to be due to drinking the water of the public wells of the city, the chemist of the Department of Health, DR. E. H. BARTLEY, has examined about fifty of the well-waters, and has found that very few of them are fit for use as drinking water. About ninety per cent. of them are condemned on account of distinct evidence of their contamination by sewage, and the Common Council has been requested to cause the filling in of the condemned wells. Even the best of the wells are much inferior in purity to the regular Ridgewood water supply. The number of the public wells is being gradually reduced.

SALE OF OVERFED POULTRY.—The Commissioner of Health has been authorized by the Board of Aldermen to enact and enforce such measures as will protect the public against the sale of gorged or overfed poultry.

DENTISTS' LIABILITY.—In a suit recently decided by the New York Marine Court, General Term, Judge McAdam writing the opinion of the Court, the liability of dentists to their patients is stated. The suit was brought by Thomas J. Kelly to recover damages from Gardner B. Colton and Louis M. Colton for injuries caused by allowing a piece of a tooth which was being extracted to drop down the plaintiff's throat while he was under the influence of laughing gas. The piece slipped from the forceps, and for four weeks thereafter the plaintiff was troubled with a cough until he finally coughed up the piece. The Court holds that while a patient is under the influence of an anæsthetic which deprives him of the use of his faculties, the operator is bound to exercise the highest professional skill and diligence to avoid every possible danger, and in this case it is the opinion of the Court that on the trial the circumstances shown were sufficient to carry the case to the jury on the question of negligence.

The judgment appealed from was in favor of the plaintiff for $500 damages, and this judgment is affirmed by the present decision.

INTERNATIONAL CONGRESS FOR THE ADVANCEMENT OF SCIENCE.—At a recent meeting in Montreal it was suggested that an international congress of the British and American Associations for the Advancement of Science be held in New York or some other desirable point in 1884.

ILLEGAL PRACTITIONERS.—Two physicians—alleged quacks—in New York City have been fined for practising medicine illegally; the Medical Society of the County making the complaint on which the case was brought to prosecution.

RICHMOND.

(*From our Special Correspondent.*)

The Medical College of Virginia Trouble is in abeyance. The old Faculty and old Board of Visitors are still in possession, and it is not likely that an issue between them and the newly appointed board will be made before spring, when the case will probably come before the Courts.

LONDON.

(*From our Special Correspondent.*)

The Physics of the Circulation.—I was present last night at a lecture given by Prof. Lister to the members of the University College Medical Society, of which Society Prof. Lister was the president when he was a student at this hospital. The Society which is a very flourishing one, has during recent years had a special meeting in October, when it has asked some distinguished teacher to deliver a lecture. An account of Mr. Lister's lecture may interest your readers, but it is only fair to observe again that it was intended for students.

Mr. Lister then began by referring to the great value of the knowledge of the simpler physical laws in the study of physiology and in practical medicine, and deploring the fact that a knowledge of physics was still not insisted on by many of our qualifying boards, he stated his intention of pointing out some of the practical bearings of the laws of hydrostatics and hydraulics. He first reminded us of the fact that if fluid is poured into two communicating tubes it will always stand at the same level in each, whatever the relative size of the tubes may be, because fluid pressure is equal and opposite in all directions. Then he explained to us the "Hydrostatic Paradox," and the mechanism by which a small column of water is made to raise a heavy weight placed upon a communicating chamber of much greater area than the column, then naturally referring to the Bramah Press. As an illustration of the working of this physical law, he introduced the application of a graduated compress to a wound of the palmar arch. It was necessary to have the apex of the compress exactly on the wound of the artery, for if it were not the wound would be converted into a Bramah press, and the small force of the escaping blood would be multiplied into one great pressure which would either succeed in displacing the compress, or in distending the loose tissue.

Mr. Lister then passed on to speak of fluids in motion, and he used a simple apparatus for his experiments. It consisted of a vessel containing colored water raised upon a high stool; from this vessel passed a long rubber-tube which terminated in a small glass nozzle. The tap in the tube was turned and the height to which the fluid was projected was noted: 3 or 4 feet of the central part of the tube were then replaced by an equal length of a tube of double the diameter and four times the capacity, and again the height of the jet was noted—the same as before. It was then shown that the interposition of a larger tube in a smaller did not increase the difficulty of forcing on fluid, and therefore it was a great error to say or think that varicosity of veins caused an impediment to the circulation of the blood.

Next the tube was raised to various heights between the glass nozzle and the glass reservoir and also depressed, and this shown to have no influence upon the force with which the fluid escaped. Thus it was proved that by mere hydraulic laws the position of any part of the body could not influence the circulation except in so far as a slight yielding of the veins might be effected when in a dependent position, reminding us that raising the head of a person much debilitated from long illness may cause syncope from anæmia of the brain, and that depressing the head of a faint person will infallibly cure this condition and cause more blood to flow through the brain.

Mr. Lister also asked how this was to be explained, seeing that the brain was contained in a closed cavity, and that under the action of gravity it would be the veins rather than the arteries which would yield and dilate. To explain these effects, the following experiments were referred to: Many years ago he had had a horse slung so that he could be placed in any desired position; he then laid bare one of the metatarsal arteries, and observed that when the hoof was depressed the wound bled freely, and that the artery was large and pulsated forcibly; while if the horse was inverted with his hoof uppermost, the wound ceased to bleed and the artery shrunk and its pulsations were not visible; that this could not be explained by the alteration in the blood pressure was clear from the fact that, as pointed out by H. Hales, the blood pressure in the carotid of a horse would raise a column of blood seven feet, and the alteration in position was not to half this amount. Again, when a large artery like the femoral was exposed for the purpose of putting a ligature on it, the vessel was seen to be of constant calibre unaltered by the ventricular systole, and yet the blood pressure was double at the systole to what it was in the diastole. He had demonstrated this some years ago by a very ingenious experiment. A glass tube with an exceedingly fine orifice was fastened into the external carotid artery of a calf and inclined at an angle of about forty-five degrees.

The fine jet of blood was then made to fall on a sheet of white paper, the lower edge of which was 11½ inches from the calf; as the paper was steadily moved along, a tracing of the blood pressure by the blood itself was obtained; this was in the form of very bold curves, which, when measured, showed that during the contraction of the ventricle the blood-pressure was double that during its diastole. But yet, in H. Hale's original experiment, the blood only oscillated a few inches in his long glass tube, and in pulse-tracings, given in physiological works, the effects of the heart are shown by shallow notches only, while the effect of respiration was marked by a bold, free curve. This, Mr. Lister explained, was due to the fact that in these apparatuses a certain length of time was required for the systole to record its effect, and before this elapsed the diastole followed.

The last experiment was in the form of a demonstration on one of the students. Baring the two arms, the right was raised vertically and the left held dependent. In a few moments the former became pale, the latter turgid and red. An elastic band was now quickly placed around the upper part of the right arm to prevent any blood passing to the parts below. After a short interval this band was removed, and although the arm was still held up it became redder than its dependent fellow. Mr. Lister deduced from these facts that when any part is raised its vessels contract in obedience to a stimulus conveyed through the vaso-motor nerves, possibly excited by the slight dilatation of the veins which occurs at first; but when tissues are deprived of their supply of blood for a given time, the demand for it is so urgent that by means of the same nervous mechanism all the arteries are dilated, even in spite of the position of the part. So, when an artery is ligatured in its continuity, the part below is at first blanched and cold, but soon it becomes reddened and warm from the dilatation of all its bloodvessels. But the change in calibre of vessels produced by pressure may spread to neighboring parts, and accordingly raising the legs will cause contraction of the pelvic bloodves-

sels and give relief in cases of piles and many other diseases of the pelvic viscera. In cases of epistaxis raising the arms will cause contraction, not only of the arteries of the arms but also of the Schneiderian mucous membrane, which is often sufficient to stay the bleeding.

Thus was shown that the cause and cure of fainting could not be explained on merely hydraulic principles, but was evidently dependent upon this vital law by which raising a part caused contraction of its vessels through the vaso-motor nerves stimulating the circular muscular fibres of the arteries.

Mr. Lister had no time to give further illustrations of the use of physical knowledge. I think this lecture may interest your readers, particularly as it shows that Prof. Lister is not by any means a man of one idea who can only speak on "antiseptic" surgery.

The medical world is now in full activity. The schools have commenced, and rumor says that the entries of new students are hardly up to the average of recent years. The various medical societies are beginning their meetings, the Clinical Society leading off on Friday, Oct. 13. I shall endeavor to send you early notice of anything of special interest recorded at either of these societies.

VIENNA.

(From our Special Correspondent.)

PREGNANCY AT AN EARLY AGE.—A girl, *thirteen* years old, native of lower Austria, belonging to the peasant class, was admitted into Prof. Braun's obstetric clinic, in Vienna, upon Sept. 29th, in her first pregnancy. She had menstruated three times before conception occurred, and the menstrual discharges were said to have been profuse. The girl was slightly developed even for her age.

Abdominal examination revealed pregnancy in the ninth lunar month, vertex presentation. The pelvic measurements were as follows:

Distance between anterior superior spine of ilia,	24 cm.
Distance between crests of ilia,	25 "
Distance between great trochanters,	29 "
External conjugate diameter,	18 "
Internal conjugate diameter,	10 "
Conjugata vera,	8 "
Pelvic circumference, measured from spine of last lumbar vertebra, between trochanters and crests,	74 "

Vaginal examination revealed vertex presentation, first position.

Labor pains were felt at 6 o'clock P.M., Sept. 28th, the bag of waters ruptured at 8 o'clock A.M., 29th; birth of a male child weighing 2370 grammes, length 45 centimetres, followed at 12.30 o'clock P.M. Placenta was delivered a few moments later.

The mother has fully recovered and will soon leave the hospital with an abundant secretion of milk. The child is living and thriving.

ERROR IN DIAGNOSIS.—Within the last few days, Prof. Chrobak had occasion to call the attention of his class to an infrequent error in gynecological diagnosis.

A woman presented herself to him, with an excessively fetid vaginal discharge, which the accompanying letter of a famous Vienna gynecologist attributed to an ulcer upon the cervix, which he had labored for weeks, in vain, to cure by caustics, applied through Braun's hard-rubber speculum.

Prof. Chrobak, after a careful examination, withdrew from the vagina a sponge, with an excavation, neatly etched in its center, corresponding to the extremity of Braun's speculum, and doubtless mistaken by the zealous practitioner for a cervical ulcer; with the removal of the sponge, a large quantity of dammed-up menstrual fluid escaped, and the supposed ulcer instantly disappeared.

DR. WILLIAM F. NORRIS.—Americans generally, and Philadelphians particularly, studying medicine in Vienna, have been properly gratified by the flattering reception which has been accorded to Professor William F. Norris, M.D., upon his present visit to Vienna. Professors Stricker and Arlt have vied with each other in doing honor to their former pupil. Stricker, with his experiments upon cerebral localization, performed out of semester time and upon monkeys, and Arlt, with his specially arranged cataract operations, have evidenced in a substantial manner their high respect and esteem for the distinguished foreigner. This expression of good feeling is especially worthy of note as occurring in Vienna, a city proverbially slow to recognize merit in foreign physicians.

PROGRESS OF YELLOW FEVER.—The Surgeon-General of the Marine-Hospital Service gives the following *mortality for the week ending October 28, 1882:*

BROWNSVILLE, TEXAS.

Among the new cases at Pensacola were the collector of the port, Tarbell (who is also mayor of the city), and his son. The latter died on the 27th inst.

SMALLPOX IN SOUTHERN AFRICA.—Capetown and its vicinity have been suffering during the past two months from an epidemic of smallpox such as is seldom recorded in these days of general vaccination. At latest dates about four thousand cases had occurred, while the disease shows no sign of decreasing. On September 18th, 114 cases were reported and on the 19th, 144 cases. It is estimated that one-tenth of the population have been affected. Fifteen per cent. of the cases have died. The people are averse to vaccination and the authorities have made no headway in checking the spread of the disease. The foreign shipping in the docks and harbor is largely infected.

DISEASE FROM UNCOOKED PORK.—An outbreak of trichiniasis occurred in Brunswick, Germany, during

the first week of October. Two hundred cases, many of them severe, were officially reported. They originated in the consumption of sausage prepared in a meat shop of good repute. The city authorities endeavor to protect the people against accidents of this kind by a system of inspection at the slaughter-houses, but this occurrence appears to have demonstrated the inefficiency of the inspections. An investigation has been ordered.

ANNUAL REPORT OF THE SURGEON-GENERAL OF THE U.S.A.—From the advance sheets of the annual report of the Surgeon-General, U. S. A., we learn that the average number constantly on sick report during the year was nine hundred and forty-two, or forty-five per thousand of mean strength.

Of these, seven hundred and sixty-two, or thirty-seven per thousand of strength, were constantly under treatment for disease, and one hundred and eighty, or eight per thousand of strength, for wounds, accidents and injuries.

The total number of deaths from all causes reported among the white troops was two hundred and sixteen, or ten per thousand of mean strength. Of these, one hundred and forty-one, or seven per thousand of strength, died of disease, and seventy-five, or three per thousand of strength, of wounds, accidents and injuries.

The proportion of deaths from all causes to cases treated was one to one hundred and sixty-one.

The manuscript of the third volume of the Surgical History of the War of the Rebellion is now sufficiently advanced to allow the volume to be completed and laid before Congress during the coming session if no unforeseen delay in the printing occurs.

The Army Medical Examining Board during its session examined 216 candidates, of which there were found qualified 39, rejected 51, withdrew after partial examination 126.

The great necessity for a fire-proof building suitable for the proper accommodation of the Army Medical Museum collection and the library grows, yearly, more imperative.

The present building is over-crowded and unsuitable for the purposes intended, while its general insecurity against accident and fire, places in extreme jeopardy collections which, if destroyed, would be an irreparable loss not only to the United States, but to the world.

The museum has attained a world-wide celebrity; is second to none in the number and value of specimens illustrating military surgery and the diseases of armies, while its sphere of practical usefulness to the medical profession of the country is unlimited.

It is therefore hoped that Congress may be induced to appreciate its great value and importance and provide for the fire-proof building required to place the collections beyond the chance of loss or injury.

The Library of this Office is devoted entirely to medicine and its branches; no purchases being made of books belonging to general or miscellaneous literature. The works in it are not duplicated in any other library in Washington, excepting only those copy-right American medical books of which specimens are deposited with the Library of Congress. Many of these are also presented to this library, so that this small duplication causes very little expense. No advantage would accrue from merging this Library with any other; its size and importance, and the demands made upon it being such as to require the services of a specially skilled medical officer to make it as useful as it should be, and to preserve for it the interest of the medical profession of the country to which much of its completeness is due.

The additions to the Library during the past year include about three thousand two hundred volumes, and three thousand five hundred pamphlets, making the total number in the collection about fifty-seven thousand volumes, and sixty-three thousand seven hundred pamphlets.

The printing of Volume III. of the Index Catalogue has been completed and the edition distributed. This volume ends with the end of letter D. The manuscript of Volume IV., which will include the letter E and part of F, is nearly ready, and the first part of it is now going to press. The use of the Library by the medical profession throughout the country is steadily increasing, and the requests for information made upon it involve much research and extensive correspondence. Over three hundred such requests were received during the year, coming from all parts of the United States, and the total number of letters sent from this branch alone was over one thousand.

An estimate has been forwarded for printing Volume V. of the Index Catalogue, and it is specially desirable that this appropriation be granted in order that no delay may occur in the issue of this work, the practical value and utility of which becomes more and more apparent as successive volumes are published.

MICHIGAN STATE BOARD OF HEALTH.—The regular quarterly meeting of this Board was held October 10, 1882, at Lansing, there being present, Hon. Le Roy Parker, of Flint, President; Rev. D. C. Jacokes, of Pontiac; Dr. H. F. Lyster, of Detroit; Dr. J. H. Kellogg, of Battle Creek; Dr. H. Hazlewood, of Grand Rapids, and Dr. Henry B. Baker, Secretary.

The President read his annual address, reviewing the work of the Board, and suggesting work for the future in the line of securing the introduction of text-books on hygiene in the schools; greater attention by localities to the pay of health officers; and some amendments to the public health laws, etc.

The Secretary presented his quarterly report of work in the office, and annual report of property for the fiscal year ending September 30, 1882.

The Secretary presented a communication relative to wounds from toy-pistols, describing the pistols and the nature of the cartridges as determined by analyses, also a report of several cases of lockjaw and death following toy-pistol wounds. He also presented a *résumé* of the works of other State Boards of Health. He also presented the statement that the immigrant-inspection service in this State had been continued through October on a reduced scale, impairing its efficiency, and he was requested to urge, on behalf of this Board, the continuation of the service through the winter with the same force as in the past summer, because this Board believes there is great danger that smallpox will be introduced by immigrants from the lower Canadian provinces.

A committee was appointed, on request of the warden of the State House of Correction and Reformatory, at Ionia, to examine the plans of desired buildings at that institution.

Dr. Lyster reported in preparation a paper on the present knowledge of typhoid fever, and he was requested to prepare his paper in the form of a document for publication in the report, and for distribution. In this connection Dr. Baker presented two diagrams showing for the years 1877–1880 the relations of deaths from that disease to population, from which it appears that the common opinion among physicians, that this disease prevails mostly between the ages of eighteen and thirty-five, and that there is little danger after forty, is not sustained by facts. A greater proportion have typhoid fever at the ages between sixty and eighty than at any other age in life.

Dr. Lyster and Mr. Parker presented, and they were

requested to complete, a report on the recent epidemic of smallpox at Flint, and they were requested to include Dr. Mulheron's report of the same outbreak.

The Secretary was authorized to issue the circular to correspondents, relative to diseases in Michigan in 1882, and the circulars and blank forms for annual reports of health officers, and of clerks of local boards of health.

The subject of compulsory registration of plumbers was referred to Mr. Parker and Dr. Lyster for the purpose of bringing it before the Legislature.

The Committee on Sanitary Conventions was authorized to make arrangements for a convention at Muskegon, about the last of November, or first week in December.

The Secretary was authorized to purchase a Thomson's quadrant electrometer, and by means of it to enter upon the observation of atmospheric electricity.

Dr. Kellogg was requested to prepare a paper on physical culture.

Mr. Parker presented a proposed bill making it a criminal offence to communicate a contagious disease, and it was ordered published in the annual report for the purpose of bringing it before the legislature.

Dr. Baker reported that he had been informed of the suspicious illness of some cattle at the State Fair in Jackson, and that other cattle which had been exposed had been taken to the fair at Grand Rapids. On his information, Dr. Murray, Secretary of the State Cattle Commission, had investigated the subject, and believed the disease to be Texas cattle disease.

In Detroit, it was stated, it was proposed to erect a "flame-ventilated" smallpox hospital, as proposed by Dr. Wight, the health officer. Members questioned the practicability of the plan, and it was referred to a committee.

A committee, consisting of Mr. Parker and Rev. Mr. Jacokes, was appointed on a plan for the regulation of medical practice.

Dr. Kellogg suggested some action by the Board relative to having sanitary science taught in Michigan colleges.

Mr. Parker presented a report of the meeting of the American Social Science Association, presenting abstracts of the several papers on health subjects.

After transacting routine business, the Board adjourned. Its next regular meeting will be held on January 9, 1883.

INDORSEMENT OF NATIONAL BOARD OF HEALTH.—The following resolutions were unanimously adopted by the Sanitary Protective Association of Newport, R. I., at its regular monthly meeting, October 12, 1882:

Whereas, The good that was seen effected by the National Board of Health in protecting the country from the entrance and spread of infectious and epidemic diseases, in aiding State and local boards, and in stimulating them towards a more energetic performance of their duty, in investigating into the true nature, causes, and methods of reproduction of zymotic disease, in collecting and generalizing mortuary and health statistics, in giving a sense of greater security to every citizen, and in exciting all classes of society to a more intelligent appreciation of sanitary needs, has been from its first establishment well known to the members of the Sanitary Protective Association of Newport, R. I., as individuals, and to the Association as such; and

Whereas, The city of Newport has especial reason for gratitude to the National Board for its prompt action in response to the requests of the Association, in obtaining a change of the quarantine ground from its dangerous position in shore to a location more remote, and in making a thorough house to house inspection of the city; therefore,

Resolved, That the Sanitary Protective Association has perceived with regret the check that has been temporarily given to the usefulness of the National Board of Health by the failure of the Forty-seventh Congress to grant the requisite annual appropriation.

Resolved, That the Association is confident that this failure to supply its usual support to the Board has been owing to a misapprehension by Congress as to the importance and necessity of the functions of the National Board, the amount and value of the work it has accomplished, the assistance it has rendered to commerce through removing, lessening, or simplifying the restrictions previously upon it, and the cost of employing skilled agents competent to perform their various and responsible duties.

Resolved, That the Association sympathizes with the Board in its present disabilities, fully endorses its usefulness and activity in the past, and expresses the hope that at the coming session of Congress such action may be taken as will relieve it from its present embarrassments and insure it a better appreciation in the future by the representatives of the people whom it benefits and guards.

Resolved, That the above resolutions be transmitted on behalf of the Association to the Secretary of the National Board of Health, to be used as may best serve the interests of public sanitation.

ACTION OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY WITH REFERENCE TO THE ARMY MEDICAL MUSEUM AND LIBRARY.—At the last stated meeting of the Philadelphia County Medical Society the following preambles and resolution were unanimously adopted:

Whereas, There is reason to fear that at the next session of Congress an effort will be made to destroy the identity of the great Medical Museum and Library at Washington, by merging them into the general Congressional Library, and placing them under the control of the latter; and

Whereas, Under their present management this Museum and Library have grown to be the most valuable collections of their kind in the world, and are consequently of incalculable value to the cause of medical science, thus rendering their preservation and progress objects of deep interest to the medical profession of this country; therefore

Resolved, That the Philadelphia County Medical Society earnestly but respectfully requests the Honorable Senators and Representatives of Congress to make no change in the present management of the Army Medical Museum and Library, but would earnestly urge upon Congress the importance of providing a commodious fire-proof building in Washington for better preservation and protection of these invaluable collections.

THE KINGS COUNTY MEDICAL SOCIETY AND THE NEW YORK CODE.—The following is the text of the resolution offered by Dr. E. R. Squibb, and which was made the special order of business at the stated meeting in November, of the Kings County Society:

Whereas, It is known through the delegates of this, The Medical Society of the County of Kings, to the Medical Society of the State of New York, that the latter body did, at the annual meeting in February last, first discuss the abrogation of the entire Code of Ethics, and, that proposition having failed, did adopt the report of its Committee on the Code of Ethics, whereby that part of the Code which relates to consultations was not only practically abrogated, but a clause was substituted declaring that "members of The Medical Society of the State of New York, and of the medical societies in affiliation therewith, may meet in consultation legally qualified practitioners of medicine," which is in direct opposition to the former Code and to the Code of the American Medical Association; and

Whereas, This Medical Society of the County of Kings is in affiliation with, and is represented in both the Medical Society of the State of New York and the American Medical Association, it now finds itself with two Codes of Ethics which are in direct opposition upon the important subject of consultations, and with a by-law enforcing the Codes of both these bodies. If this County Society obeys the legislation of the State Society, it must give up its affiliation with the National Association; while if it holds to the Code of the National Association, it must lose its right of representation in the State Society by this rejection of its by-laws; therefore, be it

Resolved, That this Society earnestly desires to retain its relations with both the State Society and the National Association, and, if possible, will do nothing to sacrifice its right to representation in either body.

Resolved, That this Society deprecates the principle of the State Society taking revolutionary action upon matters of general and important professional interest without consulting the wishes of its constituent county medical societies directly upon the points to be legislated upon.

Resolved, That this Society regrets the action of the State Society in regard to this clause in the Code of Ethics, and respectfully asks that the action may be reconsidered and reversed at the next annual meeting.

Resolved, That this Society is in favor of having a Code of Ethics, and of having one that may be in substantial accord with the principles of the old Code of the State Society and the present Code of the American Medical Association.

Resolved, That a copy of this preamble and resolutions be forwarded by the delegations of this Society both to the State Medical Society and the American Medical Association, and that the said delegates be instructed to vote on this subject in the interest of these resolutions, upon whatever issue may arise concerning Codes of Ethics or their abrogation, because these resolutions express the will of a majority in the Society to be represented by said delegates.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.—At the annual meeting held October 23d, the following officers were elected for the ensuing year:

President.—David Webster, M.D.

Vice-President.—Andrew H. Smith, M.D.

Secretary.—Dr. Wesley M. Carpenter.

Treasurer.—Dr. Orlando B. Douglass.

Censors.—Drs. J. D. Bryant, H. B. Conrad, F. R. Sturgis, Daniel Lewis, W. R. Gillette.

Delegates to the Medical Society of the State of New York.—Drs. J. W. Howe, F. P. Foster, E. Gruening, D. Lewis, A. Gerster, R. M. Fuller, J. S. Warren, A. V. B. Lockrow, W. F. Mittendorf, D. Webster, C. L. Dana, A. H. Smith, J. H. Ripley, S. Sexton, P. F. Mundé, C. S. Bull, E. L. Partridge, W. M. Carpenter, L. Johnson, V. P. Gibney, O. D. Pomeroy, A. Hadden, W. T. Alexander, G. B. Fowler.

CLINICAL SOCIETY OF MARYLAND.—The following officers have been elected for the session of 1882–83:

President—Dr. Samuel Theobald.

Vice-President.—Dr. B. B. Browne.

Recording Secretary.—Dr. J. W. Chambers.

Treasurer.—Dr. T. A. Ashby.

Corresponding Secretary.—Dr. Randolph Winslow.

Executive Committee.—Drs. J. Edwin Michael, I. E. Atkinson, and George H. Rohé.—*Maryland Medical Journal*, October 15, 1882.

FEMALE OBSTETRICIANS AT THE PHILADELPHIA HOSPITAL.—At the recent election of visiting physicians at the Philadelphia Hospital, Blockley, two female physicians were appointed by the Board of Guardians on the Obstetric Staff of the Hospital.

THE STUDY OF ANATOMY IN THE STATE OF MARYLAND.—Two important laws have recently been passed by the Maryland Legislature, legalizing the practical study of anatomy and providing for the use of bodies, as subjects, of persons who would otherwise be buried at the public expense.

THE JOHNS HOPKINS MEDICAL SCHOOL.—It is announced that the Trustees of the Johns Hopkins Hospital intends to open that institution and the medical school to be connected with it, in the fall of 1883.

RECEPTION TO PROF. S. D. GROSS.—Drs. J. Marion Sims and Harry Marion Sims gave a large and brilliant reception to Prof. Gross on Thursday evening at the Brunswick, New York.

SCARLET FEVER IN LONDON.—London is at present visited by a serious epidemic of scarlet fever. On the 10th ult., there were 593 cases of fever, principally scarlet fever, in the Asylums Board's hospitals.

PERSONAL.—DR. LEO GERLACH has been temporarily appointed "extraordinary" Professor of Anatomy in the University of Erlangen.

PROF. PAUL VOGT has been called to Greifswald, in Hueter's place.

PROF. HUEBNER will succeed Erb, in Leipzig, who has been called to Heidelberg to the chair rendered vacant by the death of Prof. Friedreich.

THE PROMOTION OF THE STUDY OF PHYSIOLOGY.—By the will of the late PROF. F. M. BALFOUR, $5,000 is bequeathed to Dr. Michael Foster, to be applied by him to the promotion and encouragement of the study of physiology.

DR. C. R. AGNEW ON ETHICS.—In the October number of the *New York Medical Journal* is a long and labored article by Dr. C. R. Agnew, of New York, on the Limits of Medical Ethics. Some time since a learned metaphysical essay upon the same topic, by a well-known lay scholar of the State of New York, was given to the profession in a communication addressed, if we mistake not, to Dr. Agnew. In June last Dr. A. attended the meeting of the American Medical Association at St. Paul as a representative of the "new departure" in medical ethics made by the State Medical Society of New York. The attempt to carry such "reforms" into the national Association met with an overwhelming rebuke from that body. The voice of the Association was of no uncertain tone. The temper of that assemblage on this subject was manifest from the beginning to the close of the session. The meeting was largely attended, and its representation was thoroughly national in character. Dr. Agnew must have keenly felt the rebuke to the movement he was so earnestly pressing on the profession in the enthusiastic declaration of so large and respectable a body of his professional brethren.

Since that time the county societies of the State of New York, whose delegates compose a majority of the State Society, have unequivocally repudiated and rescinded the action of last year which established the new code. Even the homœopaths—and for all we know, the eclectics and clairvoyants—have declined to accept the privileges afforded by the wide latitude which the new code confers upon consultations; and yet, after all this, Dr. Agnew continues to urge the movement on the attention of the profession.

The article before us has this tragical motto at its

head: "Where liberty is gone, life grows insipid and has lost its relish.—ADDISON." It purports to be a reply to Dr. E. R. Squibb's able article upon the new code, which appeared last July, but it is in the main a recapitulation of the old, illogical arguments for abolishing the Code of Ethics. The claims that gentlemen need no laws to govern their intercourse with one another, and that nothing but good can come from the utmost freedom in consultation, are here renewed, with the familiar illustrations. He advocates consultations with all classes of irregular practitioners, and favors the adoption by Congress of Senator Cameron's resolution making it an offense to discriminate in favor of any "school of medical practice" in the appointment of candidates for medical service in any of the departments of the Government. He alludes to the "Old School of Medicine" when meaning the medical profession, and complains of the restrictions of the Code of Ethics of the American Medical Association.

There is only one feature of the entire matter to which we desire to direct attention at this time. We have called attention particularly to the fact that the great objection made to *the* Code is its restrictions in the matter of consultations. So far as liberty is concerned in general professional relations with the public, the profession, and patients, we can not see how objection could be offered to that admirable application of the golden rule. It is the part which relates to consultations which furnishes the theme of Dr. Agnew's article, and to which our brethren in New York have from the beginning directed their attack. When it was observed that the most prominent and active advocates of the new code at that slimly-attended meeting of the New York State Society in which it was adopted were prominent specialists, the suspicion arose in every mind that a desire for consultation with irregulars for the pecuniary advantage it would give, prompted their action. That this was the true motive of their conduct was freely charged, and it was indignantly repelled by the organ of the new departure in medical ethics.

Now, we would ask, is this persistence in urging the matter on the profession, in the face of the events of the past six months, calculated to remove this impression from the mind of that large and respectable body known as the medical profession? The profession of the entire country has expressed in unqualified terms its views and purposes relative to the movement inaugurated by the New York specialists, and it only remains for the advocates of the new code to accept the situation gracefully or to go out among the irregulars. One horn of this dilemma is inevitable.—*Louisville Medical News*, October 21, 1882.

HEALTH IN MICHIGAN.—Compared with the average of reports for the months of October in the preceding five years, all diseases named in this report, except influenza, puerperal fever, and smallpox, were less widely prevalent during the week ending October 21, 1882, than usual.

The reports of the State Board of Health for the week ending October 21, 1882, indicate that rheumatism, dysentery, remittent fever, and influenza, have increased, and that inflammation of the bowels has decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending October 21st, and since at twenty-two places, scarlet fever at eleven places, and measles at three places. Smallpox was reported at Niles October 21.

OBITUARY RECORD.—Died, on September 23, in Göttingen, the celebrated chemist PROF. FRIEDREICH WÖHLER, in the 84th year of his age. Prof. Wöhler commenced his chemical studies in Heidelberg with Gmelin, and for a year worked with Berzelius in Stockholm. In 1825 he went to Berlin, and in 1827 was elected Professor in the newly founded "Gewerbeschule," where he discovered the elements aluminium and beryllium. After living for five years in Cassel, he was called in 1836 to Göttingen, where he remained up to his death. He was associated with Liebig in editing the "*Annalen der Chemie und Pharmacie*," and with Poggendorff in the "*Annalen der Chemie und Physik*." His text-book of chemistry has had a wide reputation.

——On September 14, in Paris, GEORGES LECLANCHÉ, in the 44th year of his age. M. Leclanché is best known as the inventor of the peroxide of manganese battery which bears his name.

NOTES AND QUERIES.

DR. REITERS' REMEDY IN SCROFULA.

To the Editor of THE MEDICAL NEWS.

Dear Sir: Amongst the editorials in THE NEWS for October 7, there is one in regard to Dr. Reiter's remedy for inveterate psoriasis by the use of a saturated tincture of burdock seed. I wish to add my testimony to its efficacy in that class of cases usually termed scrofulous. About eighteen years ago, an old lady cured a patient of mine—a boy, five years old, who had been suffering from enlarged and suppurating glands in the cervical region, which had resisted all the usual tonic and alterative remedies—in about six weeks, by giving teaspoonful doses of the saturated tincture three times a day. I have since found it to be nearly a specific in that form of trouble, and in that condition of system characterized by a scaly eruption on the scalp and indolent ulcers behind the ears, occurring in unhealthy children, it almost invariably gives prompt relief. The tincture of the root will not do.

Respectfully,
W. H. CYRUS, M.D.

NOBLESVILLE, Ind., October 23, 1882.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 23 TO OCTOBER 30, 1882.

TURRILL, HENRY S., *Captain and Assistant Surgeon.*—Assigned to duty at Fort Omaha, Nebraska.—*S. O. 112, par. 3, Department of the Platte, October* 23, 1882.

BANISTER, JOHN M., *First Lieutenant and Assistant Surgeon.*—The leave of absence granted by par. 5, S. O. 203, Department of the Missouri, October 10, 1882, is extended one month—*S. O. 113, par. 2, Military Division of the Missouri, October* 23, 1882.

WILSON, GEORGE F., *Assistant Surgeon.*—Is relieved from duty at Vancouver Barracks, Washington Territory, and assigned to duty at Fort Townsend, Washington Territory.—*S. O. 148, par. 1, Department of the Columbia, October* 6, 1882.

OWEN, WM. O., JR., *Assistant Surgeon.*—Is relieved from duty at Fort Townsend, Washington Territory, and assigned to duty at Vancouver Barracks, Washington Territory.—*S. O. 148, par. 1, Department of the Columbia, October* 6, 1882.

BUSHNELL, GEORGE E., *First Lieutenant and Assistant Surgeon.*—Extension of one month's leave of absence is revoked.—*S. O. 247, par. 2, A. G. O., October* 23, 1882.

KANE, JOHN J., *Assistant Surgeon.*—Whose leave of absence granted October 9, 1882, Department of the Missouri, is extended two months.—*S. O. 247, par. 3, A. G. O., October* 23, 1882.

WYETH, M. C., *First Lieutenant and Assistant Surgeon.*—Will be relieved from duty at Fort Meade, Dakota Territory, upon his return from detached service and will proceed to Fort Yates, Dakota Territory, and report to the commanding officer of that post for duty.—*S. O. 172, Department of Dakota, October* 19, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

THE TREATMENT OF PNEUMONIA.

A Clinical Lecture delivered at the University Hospital.

BY WILLIAM PEPPER, M.D., LL.D.,

PROVOST AND PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

(*Specially reported for* THE MEDICAL NEWS.)

IN a simple uncomplicated case of pneumonia, the result of a single exposure to cold, we have the best chance to study the therapeutics of this interesting disease. If it be seen in the beginning, the line of treatment should be decided upon at once, for the final result of an attack depends largely upon its management during the first forty-eight hours.

The first effort must be directed toward limiting the area of lung structure which will pass into a state of inflammation; in fact, to limit the disease. This can be done to a certain extent. There is one point where the irritation will be greatest, and there will be found the greatest amount of damage. Around this centre are areas where the damage wrought grows less and less, the further we are from the centre of the inflammatory process. Now, we cannot abort the disease in the centre, but in the surrounding areas where the inflammatory process has not progressed to so great a degree, we may so modify the process as to secure resolution in these parts.

We must enforce absolute rest of the body, and warmth and protection of the surface. The patient must not be allowed to exert himself at all. He must use the bed-pan and urinal, and must be fed by his attendant. This conservation of force is a matter of the most vital importance.

The nerves and vessels of the affected area can be influenced by local depletion. Place wet cups over the seat of pain. This stimulates the vaso-motor nerves, and causes the vessels to contract, leaving less blood in the part. If the pulse be strong and bounding, arterial pressure greatly increased, intense throbbing headache, high temperature and hurried respiration, the end sought will be more certainly secured by venesection than by any other mode of depletion. In the first stage of such cases, general bleeding is useful; but the cases are so seldom seen in their incipiency, that it rarely happens that we can resort to this measure. Still, if a case occuring in a vigorous subject presents the features above named, I have no doubt that a moderate venesection will do good.

The diet should be very restricted. Injudicious feeding and premature stimulation are very grave defects in the treatment of the early stages of acute diseases. There certainly are times when concentrated nourishment and strong stimulation are needed. Early in the case, however, a simple diet of light broth, gruel or milk, is all that is necessary. There is no danger of a person dying of inanition in forty-eight or seventy-two hours; he has his own tissues to feed upon, and he can get along very well upon a light diet, and in the early stage of pneumonia especial care should be taken to see that the stomach be not overloaded.

When there is an excited pulse and great arterial tension, veratrum viride should be administered. It may be given in doses of three drops at short intervals —say of three hours. Its effect must be closely watched. Cooling diuretic and diaphoretic drinks may be used, and quinia should be given in the early stages. If the stomach is in good condition, it may be given by the mouth in doses of four grains every four hours. It is usually well borne, and tends to limit the extent of lung which will pass into consolidation. If the stomach is irritable, great care must be used to avoid exciting vomiting, and the quinia should be given by enema.

At the end of forty-eight or seventy-two hours the evidences of consolidation are revealed. The part consolidated must go through resolution, and this we must favor. A more nourishing diet is needed, and there must be no further depletion, unless the patient be very plethoric, and there is excessive venous congestion, labored condition of the heart, and excessive bronchial secretion. But if the remedies have been used properly in the first stage, depletion will usually not now be necessary. The veratrum may now be omitted, and the salts of ammonium, especially the muriate, should be used to favor resolution, in doses of eight grains every three hours, combined with a few drops of dilute muriatic acid; and quinia should be continued in doses of two or three grains every four hours.

During all this time, the chest should be surrounded with cotton, or kept enclosed in hot mush-poultices. The patient may now have beef-tea, alternating with milk. If there be marked debility, wine whey, or a small quantity of whiskey, should be administered.

Another type of pneumonia is where there is marked gastro-hepatic derangement, with prominent bilious symptoms—coated tongue, nausea, perhaps vomiting and looseness of the bowels, the fecal matter containing undigested food; headache, insomnia, sometimes delirium, and a tendency to pass into a condition of typhoid debility. Here depletion is not well borne. Dry cups may be placed over the liver and over the seat of the inflammation. Most careful attention should be given to the condition of the stomach. Veratrum viride will often cause vomiting, and in that case it must not be used, but tincture of aconite root should be substituted, in the dose of three or four drops every hour, until it affects the pulse. Calomel and an alkali should be given from the start, the best alkali being bicarbonate of sodium. One-sixth to one-fourth of a grain of calomel, and three or four grains of the bicarbonate may be given every three hours, alternating with a dose of aconite. This should be continued until it affects the bowels, or until three to five grains of calomel have been taken. Quinia in such cases must be given by enema, or in the form of suppositories which, if properly made, are very effective.

Give whey, buttermilk, gruel, or champagne in tablespoonful doses. Treat the patient for catarrhal inflammation of the stomach and bowels as well as for the pneumonia. When the stomach is quieted and the tongue cleaning, resort to muriate of ammonium and muriatic acid.

These remarks apply to the common forms as seen in adults, but pneumonia in children presents some peculiarities as regards treatment. Quinia is well borne in comparatively very large doses; and stimulants are also well borne, and may be given at an early stage of the case. Veratrum viride should never be given to children. Give aconite in the first, and carbonate of ammonium in the second stage. I usually prefer carbonate of ammonium to the muriate in the pneumonias of

children, and especially when there are marked nervous symptoms.

In some cases stimulants are not needed until resolution is well advanced, and then only in small quantities. But there are cases where we are compelled to give them from the first, especially where there is marked nervous depression. Begin with very dilute stimulants. Opium is of great service; it may be called for in any stage, but it must always be given with great caution. Use the deodorized tincture, in combination with the muriate or carbonate of ammonium, when pain, nervousness, cough, sleeplessness, or looseness of the bowels are excessive. Do not forget that diarrhœa may readily be excited or maintained by the use of irritating remedies or injudicious articles of food when there is, at the same time, an irritable state of the bowels. When the stomach is irritable, opium may be given in suppository, along with quinia at night, quinia alone being given during the day. Ten to fifteen drops of the deodorized tincture may be given once or twice in the twenty-four hours, but if the cough is troublesome, it may be given in divided doses through the day, in combination with the salts of ammonium.

The complications of pneumonia are numerous, and require modifications of treatment, to all of which it is impossible I should now even allude. I am led, however, by the study of the case we have just seen to ask your careful attention to the importance of repeated examinations of the urine for albumen. This may be found as the result merely of congestion and increased blood pressure in the Malpighian tufts of the kidneys, and then it need not imply any great increase of danger. But when associated with the microscopic evidences of acute catarrhal nephritis, a complication by no means rare, the gravity of the case is much deepened. The same diet and the same stimulants and quinia may be used, but no blood should be drawn. Dry cups should be placed over the kidneys every day. Use repeated small doses of calomel and alkalies, and the infusion of digitalis as a diuretic. Continue this until enough calomel has been given, and then substitute muriate of ammonium and continue the digitalis. Convalescence must be watched much more suspiciously, and the patient should be compelled to remain in bed until all traces of albuminuria have disappeared. After the pneumonia has terminated by resolution, if this fortunate result occurs, the treatment suitable for subacute catarrhal nephritis may be instituted and continued.

ORIGINAL ARTICLES.

RESEARCHES ON THE EPITHELIUM OF THE CORNEA.[1]

By ERIC E. SATTLER, M.D.,
of Cincinnati, Ohio.

The cornea and its epithelium have played for a long time one of the most important *rôles* in the history of microscopy, and still serve as excellent objects for experimentation and generalization. It has become, as it were, classic ground, and many results, most generally accepted now, date their origin from observations first made on these parts.

It was according to the original suggestion of v. Recklinghausen[1] that weak solutions of various salts of silver were first used for impregnating, and thus coloring, the tissues. The method, as everybody who has used it to any extent can testify, was attended with excellent results. The solid stick of nitrate of silver was employed much less frequently for the demonstration of the more delicate tissue-structures, notwithstanding the fact that for the first experiments on the cornea with silver, the solid stick was used. Coccius,[2] Stricker,[3] Eberth,[4] and others, have used the solid stick on the cornea for observing the process of inflammation as it takes place in that structure; nothing, however, has been published to my knowledge of its use in clearly demonstrating the structure of the epithelium, and it was for the purpose of comparing the two methods that I made a series of experiments, with the results as shown in the following communication. I found that the direct application of the solid stick possesses many advantages, with none of the disadvantages, of the weak solutions of silver salts, and for a clear demonstration of the epithelium, is to be preferred to the old method. The greatest number of experiments were made on the corneal epithelium of frogs and the epithelium of the skin of batrachians. The mode of procedure is as follows: After removing the membrana nictitans of a recently killed frog, the eye is slightly pressed from the orbit with the finger introduced into the jaw, and the solid stick freely applied to the surface of the cornea until it has assumed a milky appearance. The pure nitrate stick is greatly to be preferred to the mitigated. The upper part of the head, with the eyes still remaining in the orbits, is then removed from the rest of the body, and is exposed in slightly acidulated water (formic or acetic acid) to the direct rays of the sun. This latter procedure is not absolutely necessary; as good, if not better, results may be obtained by simple exposure of the head to the sun, without the addition of the acidulated water. As soon as the corneæ have assumed a brownish color, they are carefully excised in the usual way, spread out with glycerine under a cover-glass, and looked at with a high power. The stick of silver may also be used on the living frog in the same manner as above, and beautiful specimens sometimes obtained in this way. On sunny days, fifteen to thirty minutes are all that is required to complete the whole procedure. A somewhat longer time is required on cloudy days. I have in many cases made excellent preparations in the short space of ten minutes.

The intercellular cement substance remains clear and unchanged, while the protoplasm of the cells assumes a light or dark-brown color, according to

[1] This article will appear in German in the next number of the "Archiv für Microscopische Anatomie," and has now been translated by the author, with some alterations and additions. The experiments were made in the laboratory of Prof. Waldeyer, at Strassburg, Germany.

the intensity of the action of the silver on the tissue. The nucleus remains light, I might with propriety say white, with sharply defined outline. The nucleolus is colored in a similar manner as the protoplasm, somewhat lighter however. Sometimes the protoplasm assumes a peculiar bluish color, as if stained with hæmatoxylin. As will be seen, one of the great advantages of this method consists in the coloring and clear demonstration of all the parts of the epithelial cell, an advantage which weak solutions never possessed. It always required a second staining with some other fluid to show the nuclei and nucleoli.

What strikes our attention in the first place, in good preparations of this kind, is the sharply defined appearance of only one layer of epithelial cells, and that the most superficially situated one, its dark coloring preventing the appearance of the immediately underlying layers. It is on this account that morphological conditions can be studied with scientific accuracy, in a *single* layer and be separated from conditions found in deeper layers, a circumstance, too, which is of great advantage in estimating the number and size of cells in a given space, as will be shown later on. The dark coloring of the cells is also imparted to the peculiar connecting links, if I may so call them, between the cells, the so-called lines of Bizzozero, and these peculiar processes can be beautifully demonstrated in preparations made in this manner.

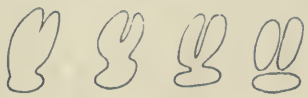
In the next place the form of the cells and nuclei claims attention. In the greatest number of cases, the outlines of the cells instead of being regular are irregular, due to peculiar projections or arms. The same feature may be noticed in many of the nuclei. These appearances give rise to an almost unmistakable impression and supposition that the cells, irritated by the application of the silver, had made amœboid movement, and had been fixed in one or the other phase of these movements. I know of no other method which demonstrates so clearly the amœboid movements of the cells and the nuclei as the direct application of the solid stick of nitrate of silver to the corneal epithelium. The nucleoli, also, stand out prominently, generally more than one being found in a nucleus. The minute structure (Kerngerüst), on the contrary, never becomes visible, therefore this method does not seem suitable for showing the "karyokinesis" taking place in the epithelial cells, yet nevertheless many interesting points can be arrived at also in this connection.

I come now to speak of the most important point, the division of the cell and nucleus, every stage of which process can be followed from beginning to end with the minutest accuracy and precision in the different specimens of the corneal epithelium obtained in this way. The peculiar karyokinetic figures, known by the Germans as "fadenknäuel," "sternfiguren," and "kernspindle," are, however, never met with. The nuclei always have the same appearances while division is taking place, as were figured by writers many years ago, *i. e.*, kidney or biscuit-shaped contracted nuclei, others only joined together by a thin thread, and finally cells with two distinct nuclei, the cells either unchanged, only increased in size, or also in a state of contraction and beginning division. I have seen several cells just on the point of division into two, each part of the cell with its distinct nucleus. Often the cells just at this stage were found in amœboid movement or violent contraction. Never, as I have remarked, do the peculiar well-known karyokinetic figures of Flemming appear, and it is surprising when we compare the always-occurring, sharply-defined figures of the division of the cell with the *stern* and *knäuel* figures made known to us by the indefatigable researches of Flemming, Strassburger, Magzel, and others, to find nothing whatever of these latter. If we seek to harmonize the results obtained by the application of the silver and those obtained by the method of staining by Flemming, only one hypothesis seems at all clear to me, viz., that the different appearance of the nuclei in the silver method is to be accounted for by the achromatic substance of Flemming. This substance is not brought out clearly by the staining method of Flemming, at least it disappears in contrast to the remarkable appearance presented by the chromatic constituents during the progress of the division of the cell. The silver method constantly shows the appearance of the entire nucleus with its chromatic and achromatic substance, which, however, cannot be distinguished from one another. We see, therefore, in accordance with the foregoing results, that the achromatic substance also shows amœboid movements during division, but in every other way takes part in this act in the simple way, as was formerly supposed. We must accordingly come to the conclusion, from the results obtained by Flemming and those by the method described in this paper, that the more fluid achromatic substance of the nucleus constantly surrounds the chromatic substance (or kernfäden) and divides in conjunction with this; and that, while the chromatin of the nucleus is successively passing through the various well-known changes of form and place, the achromatin divides in a simple manner, forming a sort of a hull around the chromatin figures. The proof for the correctness of this view would be furnished by preparations, in which, by some supplementary method of staining, the chromatic figures could be produced in the nuclei obtained by the silver method. I have tried this with various staining fluids at my command, but so far without success. Further investigations by other observers and other methods, however, might lead to some definite result, and experiments in this direction are certainly called for.

With the method detailed above, the nucleoli also show themselves, of somewhat lighter shade of brown than the protoplasm. The number found varied from one to four in one nucleus, two being probably the most constant. They varied in size, so that if two were present, one was generally smaller than the other. In accordance with the observations of Flemming, the nuclei were devoid of nucleoli as soon as division began. Again, I noticed in a great many cases evident budding and division of the nucleoli, as, for instance, nucleoli that were joined together by a thin thread only, and other forms pointing to the same thing. In

view of the present now generally accepted theory, that the nucleolus does not take part in the division of the nucleus and cell, I would like to call especial attention to these results, obtained by the silver method, agreeing as they do with theories formerly held, but in this age of rapid changes perhaps too eagerly thrown aside.

Here and there I came across an unmistakable triple division of a nucleus; that is, cells containing three distinct nuclei and nucleoli. I was able to follow the mode of division in various specimens, and shall, instead of a long description, illustrate it by the accompanying wood-cut.



Drawing showing the division of one nucleus into three.

Another peculiar advantage offered by my method of silver staining is the scientific exactness with which measurements can be made of the cells, for reasons given above. There can be no question of shrinkage of the cells. I compared the size of the cells with one nucleus with the size of those with two and three nuclei. The measurements were made with an ocular micrometer of Hartnack. The longest average diameter of those with one nucleus (result of twenty-five measurements)=0.0325 mm., shortest=0.0271 mm. Those with 2 nuclei (average of twenty-five measurements) were: longest=0.0487 mm., shortest=0.0398 mm. For two cells with each three nuclei, I found 0.072 : 0.042 mm., and 0.070 : 0.044 mm. respectively. A considerable increase in size is therefore noticed in those cells containing more than one nucleus in the various stages of division. To equal advantage we can employ this method in estimating the number of cells in division in comparison to those in a quiescent state. I know of no other method with which such accurate results in this line can be reached, for the reason that but one layer is visible, and hence cells of this layer and their outlines cannot be mistaken for those situated in deeper layers. For the cornea of the frog, after numerous countings, in the first layer of epithelium I found an almost constant ratio of 1 cell in division to 35 not so engaged. Very often I noticed a number of cells in division in close proximity, which, however, did not disturb the proportion.

In conclusion I would like to call attention to almost constantly occurring fine black lines, seemingly coming out of the intercellular cement substance, running over the protoplasm of the cell toward the nucleus, and suddenly disappearing from view as soon as they have taken their course a little beyond the edge of the nucleus. Distinct endings I have never been able to make out. Sometimes a line runs parallel to the outline of the nucleus, into which all these black lines seem to end. I have never been able to follow them to the nucleoli, as they always appear to take their end in the nucleus close to its edge. The number of these lines varies from two to ten. Often, too, the nuclei situated in a mother-cell were connected together in this way. These lines are not to be confounded with the fissures and cracks occurring in epithelial cells.

I should not like, without additional experimentation, to come to hasty conclusions, but the possibility that these lines may be *nerves* ending in the nuclei must at least be granted. I have tried, but without result, to verify these appearances with the various chloride of gold and other methods. The impregnation with the silver is so intense that an additional staining is out of the question. The appearance of the lines seems to depend on the degree of intensity with which the silver acts. Enough has been done by this little paper if it has called attention to some points still clouded by fog, and has stimulated others to continue investigations in this most interesting subject. In this way only is science advanced.

EXTENSION AS A SURGICAL REMEDY.

By JULIUS A. POST, M.D.,
of Lansing, Mich.

To my respected teacher, Prof. Sayre, I am indebted for much that has proved of assistance in my surgical labors, and not only benefited me, and been the direct agent of relieving the sufferings of many of my patients, but of giving them sound limbs and useful members to help them along the rugged path of life. While at Bellevue Hospital, in the winter of 1865–66, my attention was directed to the method of extension by the wheel and pulley, and the various apparatus and appliances for producing extension at the hip, knee, and ankle; and from that time to the present I have never lost an opportunity for applying extension, and have never been disappointed in the results.

My experience has been a pleasant one, and I would urge every practitioner of medicine and surgery to thoroughly acquaint himself with the tried and most approved methods of extension, and having become familiar with their varied workings, never to let an opportunity pass without availing himself of its almost magic power.

Thousands of crooked limbs and anchylosed joints are to be found in every section of our land, and their owners go wandering about as living, moving monuments, and not only disgrace the man whose stupidity was instrumental in producing their deformities, but are everlasting reminders of the monumental status of the old time surgeon, and *prima facie* evidence that the workings of extension were to him unknown. I well remember two cases of acute traumatic synovitis of the knee-joint which came under my observation during my student life. These two men I meet quite frequently, and as I look at them and see their crooked legs and hobbling gait, I almost blush, and I feel a nervous tremor, which I can only interpret as an evidence of pity and charity, not only for the deformed subjects of incompetent treatment, but that so little is known of the benefits to be derived from the judicious employment of extension.

My note-book is replete with cases which I have carefully studied, and in evidence of the benefits to be derived from a thorough and systematic applica-

tion of this important remedy, I will draw on them for a few cases to illustrate something of its good work. Not long since I was consulted by a medical gentleman from a neighboring town, with reference to a case of anchylosis of the knee-joint, following acute synovial inflammation. This is my apology for the present paper, and will explain the earnestness in which I labor to bring this matter before those practitioners who do not have an opportunity to observe the methods employed in hospital practice, and are not familiar with the treatment of diseased joints by extension.

One of the most marked cases, and one which interested me very much, was that of Mrs. G. She came under my observation in the spring of 1868, and on my first visit I learned something of her sufferings, and gathered the following history from her husband. Two years previous she was suddenly taken with a severe pain in the hip-joint. The pain was continuous, and extended down the thigh to the ankle, but seemed more fixed at the knee. Never for a single moment was she free from pain. Two years of continual suffering had brought her to the bed, and reduced her from a plump, rosy womanhood, to a skeleton with barely enough flesh to cover her suffering frame. Unable to stand or sit for a single moment, obliged to call assistance every time she wished to move, with an hour of quiet sleep unknown for two long years, indeed, she was an object of pity. It is needless for me to state that her medical advisers had been numerous. All agreed that she was a victim of sciatica. She had been blistered and setoned and issued, and powdered and pilled and purged, had taken great quantities of guaiac and colchicum, and dosed with almost everything known to the regular or irregular professional world. She had lived, as she stated, for months on morphia; but in spite of all this the pain still continued. She was slowly wearing away, patiently waiting for the summons to come to join the unnumbered dead.

Before visiting the bedside I had satisfied myself that sciatica was out of the question. The father and mother, brothers and sisters, were all in excellent health; noted for their vigorous constitutions and physical development. As I passed into the room occupied by the invalid, I could see that she was fully prepared to receive my instructions as to pills and powders with true Christian resignation. I found that this so-called sciatica had developed soon after a fall on the back-door step. While she was occupied with other matters I stepped to the foot of the bed and gave her a slight tap on the heel, with such good effect that she bolted upright in bed, and sounded a key-note of alarm which brought the entire household about us in dismay. I explained my position, called for a couple of bricks and some cord, attached the cord to the foot, tied it to the bricks, swung the whole affair over a roller at the foot of the bed, and in less than ten minutes she was sound asleep; she slept four hours, awoke, took some beef tea, and for the first time in two long years was free from pain. We continued the pulley at night, and the extension hip-splint during the day. In two weeks she sat up, walked about the room, and has never required any treatment except beef tea, eggs, milk, and such nourishing diet as any good housewife can place before a hungry person. She is now well, weighs 138 pounds, and thanks God every day, that extension has taken her from her seeming death-bed, and changed her to a healthy vigorous woman. So much for a case of sub-acute inflammation of the hip-joint caused by a twist of the leg while going down stairs.

It has been my lot to meet with several cases of sub-acute articular rheumatism, which have yielded speedily and kindly to the wheel and pulley. I know of no remedy so grateful to a patient who has been a long sufferer from an articular inflammation, as extension. I believe it to be a powerful agent, and in the hands of an intelligent man, in this class of cases, is capable of doing a vast amount of good.

Mr. H., aged 24, came under my care in May, 1867, for a so-called sciatica. The trouble began soon after immoderate jumping. He was in the second stage of hip-joint disease. An incision about four inches long, in the upper-third and outer-aspect of the thigh, disclosed about a quart of hard, cheesy-looking material, firmly held by the strong fibrous fascia lata. From this cavity was a sinuous passage to the hip-joint, through which the finger readily passed. A number of little, honeycombed pieces of bone came away with the cheesy substance. The wheel and pulley at night, and the extension hip-splint during the day, gave him a useful leg, about an inch shorter than its fellow, but with good motion, strong, and amply sufficient for all the practical purposes of life.

I might relate quite a number of cases, all of special interest, and each one testifying to the efficiency of extension. I have treated four cases of traumatic inflammation of the knee-joint, always using extension, and always with good results. I have yet to meet with my first case of deformity, or anchylosis, and I never expect to meet with one so long as the inflamed surfaces are kept apart.

A. C. N., aged 18, was a patient of mine with acute traumatic inflammation of the knee-joint, caused by a cut puncturing the joint. Extension reduced the inflammation rapidly, and motion, under chloroform, gave him a good leg. To-day he is an upright example of the good results of extension.

I find that I have notes of eleven cases of inflammation involving the synovial tissue of the ankle-joint, all treated with the wheel and pulley, and ankle-joint extension. I never have allowed a joint to become anchylosed, and I never shall so long as I use extension and passive motion. Extension is the sheet-anchor in joint inflammations, and so long as it is properly used I have little fear of crooked limbs and stiff joints.

Extension, as applied to orthopædic surgery, is in its infancy. The day will surely come when operative procedures, other than extension, and gradually bringing the deformed member into a normal position, will be entirely abolished. Muscles and tendons have been cut and hacked, deformities have increased, and limbs have been made permanently useless by meddlesome tenotomy. Extension has

done, and will continue to do all that the most enthusiastic tenotomist could ask for.

Another long stride in the right direction is the almost entire discarding of iron braces, and apparatus full of joints and hinges, screws and bolts, for the treatment of spinal diseases. For the past twenty years the plaster jacket has been largely in use in the treatment of spinal curvatures and disease of the vertebræ, and with a proportion of good results never before realized. The principle involved is entirely and wholly that of extension, and the only question open for discussion, is how best to apply that important factor.

In a number of cases of spinal curvatures and diseases of the spinal vertebræ, which it has been my privilege to attempt to benefit, I have employed the extension pulley and plaster jacket, with or without the jury-mast, as the case would require, and I have never met with a single case where I have been disappointed in the result of the treatment by extension. Retention of the parts in proper position is a valuable and not-to-be-forgotten consideration, but the fixation of the body without the necessary extension would be worse than useless. The paralysis of children is often relieved by the application of extension and the plaster jacket, and the use of electricity and massage, combined with fresh air and sunlight, gives the little patient a better chance to overcome whatever of disease may have fastened upon it. Faulty nutrition is thus improved, and feeble children will develop into something of better flesh and blood if given the opportunity. Fractures of the lower extremities are often treated by simple extension, the retentive appliance being nothing but two bags of sand placed along the sides of the fractured limb. Excellent results are obtained by this method of treatment. I know of no fact more deserving of attention than the one that any disease of the joints where irritation and inflammation is the result of pressure, and where pain can be relieved by extension, that remedy, extension, should be employed; and further, I am satisfied that extension is one of the most important surgical remedies.

ROUND-CELLED SARCOMA OF PROSTATE GLAND.

By H. R. WHARTON, M.D.

DEMONSTRATOR OF CLINICAL SURGERY IN THE UNIVERSITY OF PENNSYLVANIA; SURGEON TO THE CHILDREN'S HOSPITAL, PHILADELPHIA.

W. C., aged 35 years, was admitted to the University Hospital, on the evening of August 8th, suffering from retention of urine; numerous attempts had been made during the day to relieve the bladder by the use of a catheter, without success; the house surgeon after his admission also attempted to introduce a catheter, but finding that it went into a false passage, wisely desisted from further efforts.

When I saw the patient a short time after his admission, he was restless and complained of severe pain in the hypogastric region, the abdomen presented a smooth globular swelling which was dull on percussion and extended from the pubis almost to the umbilicus.

The patient stated that some years ago he had had gonorrhœa, which had been followed by a stricture, this had been relieved by the use of bougies, but for more than a year he had at times suffered from pain in passing his urine, which at no time was bloody; the present attack he said was the most persistent one from which he had ever suffered.

I first introduced a full-sized catheter into the urethra but as it approached the membranous portion of the canal, found that it slipped into a false passage; small flexible instruments were also tried without success.

On introducing my finger into the rectum I found that the prostate gland was very much enlarged. The patient was ordered a warm poultice to the abdomen, and given a suppository of belladonna and opium, to be repeated according to circumstances; in the course of an hour he was much more comfortable and had passed a few ounces of urine, and during the night passed small quantities of urine at intervals.

When seen on the following day the abdominal tumor was slightly less marked, the patient was comfortable, and was passing a fair amount of urine.

On August 13th, another attempt was made to introduce an instrument into the bladder, without success.

The patient did well until August 18th, when the abdominal tumor increased in size and he suffered from severe pain and retention of urine. The symptoms now becoming urgent, it was decided on consultation with Prof. Ashhurst, to etherize the patient and try to introduce an instrument through the urethra, and should this fail, to aspirate the bladder above the pubis, or to open the urethra through the perineum.

The patient being etherized, an unsuccessful attempt was made to introduce an instrument into the bladder; a medium sized aspirating canula was then introduced into the tumor through the abdominal walls, but no fluid was obtained except a small quantity of blood; in introducing the canula it was remarked that it gave the sensation of passing into a solid body, and after a careful examination it was evident that there was a solid tumor occupying the position of, or attached to the bladder.

It was now decided to open the urethra at the base of the bladder through the perineum, and the operation known as Cock's was selected, which consists in tapping the urethra through the perineum, with the finger introduced into the rectum and resting upon the apex of the prostate as a guide. This operation was accordingly done, and was followed by the escape of a small amount of urine, which caused some diminution in the size of the abdominal tumor and rendered its outlines and solid nature more observable. Through the rectum could be felt a smooth oval tumor behind the enlarged prostate, which was supposed to be the bulging posterior wall of the bladder.

The patient was put to bed and kept moderately under the influence of opium; he did well after the operation, and expressed himself much relieved, passing his water freely, and suffering only from an attack of dysentery, which was difficult to control, and was probably due to transmitted irritation. On

the ninth day after the operation, peritonitis suddenly developed, and caused a fatal termination of the case on the following day.

Autopsy (two hours after death).—Upon opening the abdomen, a large quantity of thick, yellowish-red, purulent fluid, having a urinous odor, was found bathing the intestines; recent lymph had been thrown out, and the coils of the intestines were everywhere bound together by adhesions, which were, however, easily separated.

The omentum was in places firmly adherent to the intestine, and contained numerous irregular nodulated masses, varying in size from that of a pea to that of a hen's egg. These masses on section presented a whitish-yellow color.

In the lower part of the abdominal cavity was a large, irregularly-shaped tumor, firmly adherent to the small intestines, omentum, colon, and pelvis.

After the separation of these adhesions, and the removal, by careful dissection, of the growth, it was found to originate from the prostate gland. On section, the tumor presented in parts the characteristics of scirrhus, in other parts those of encephaloid; in other places there were large irregular loculi, with reddened, irregular, friable walls, filled with fluid similar to the fluid found in the abdominal cavity, though no communication between these loculi and the abdominal cavity was found which might not have been made by the force necessarily used in separating the tumor from the intestines.

No trace of normal prostate gland or seminal vesicles could be discovered.

The bladder, containing a few ounces of urine, was found in front of the upper portion of the growth, its upper part almost on a line with the umbilicus.

The anterior wall of the bladder was perfectly normal; its posterior wall, resting on the tumor, was thickened, raised, red, and velvety, a condition caused apparently by the growth of numerous small villous masses in the epithelial lining, as the muscular coat did not seem to be infiltrated.

The ureters were normal and opened into the bladder in the normal position.

The urethra, as far as could be seen, ran along the anterior surface of the tumor, and was not involved by it.

The weight of the growth was five pounds and two ounces.

The kidneys, stomach, lungs, and intestines were normal; the capsule of the liver and spleen contained several secondary growths.

The brain and membranes were not examined.

Drs. G. E. de Schweinitz and W. E. Hughes, who made a microscopical examination of the tumor and the secondary growths, submit the following report:

MICROSCOPICAL EXAMINATION.—Portions from the primary growth, and also pieces from the secondary deposits in the omentum, liver, and mesenteric glands, were hardened in alcohol, sections were made, were stained with carmine, mounted in damar, and examined microscopically. The growth is a typical small round-celled sarcoma, as is shown by the uniform character of the cells, their embryonic structure, the wall-less bloodvessels, and the absence of any alveolar stroma. The secondary deposits repeat the structure of the original growth. In all the specimens the bloodvessels are numerous, being either simply vascular lamina, or else separated from the cells by a little fibrillated tissue. Many of them are filled with blood-clots. A faint, slightly granular, intercellular substance can be detected. In some specimens, here and there, old preëxistent connective tissue is seen. No prostatic structure is anywhere to be detected. The wall of the bladder, after preparation, exhibited the following characters: the epithelium of the mucous coat is proliferated and granular, the nuclei of the cells being not at all, or scarcely, distinguishable. The submucous fibrous tissue and the muscular walls are engorged with a small-celled infiltration.

Dr. Henry Formad, Assistant Demonstrator of Pathology in the University of Pennsylvania, who has examined the sections cut by these gentlemen, concurs in their opinion.

Malignant disease of the prostate gland is a rare affection; but its occurrence is probably not so exceptional as would be indicated by the statistical researches of M. Tanchon,[1] who found it present only in five instances out of 1,904 cases of males who had died of malignant disease. Sir Henry Thompson,[2] in commenting upon the above figures, states that he believes that they represent a much smaller than the true number, and bases his belief upon the errors which may have occurred, due to the source from which these figures were derived—from an ordinary register of deaths; and also, from the fact that encephaloid of the prostate gland rapidly involves the bladder, he thinks that many of the cases classed as vesical, may have had their origin in the prostate gland.

M. Jolly,[3] in a monograph upon this subject, mentions an aggregate of forty-one cases, which includes many of the cases collected by Thompson and Oscar Wyss, but the author himself thinks it is questionable whether some of the cases can properly be classed under the head of malignant disease.

Thompson reports eighteen cases of malignant disease of the prostate gland which he considers well authenticated.

Gross,[4] in speaking of tumors of the prostate, mentions cysts, fibromata, myomata, carcinomatous tumors, and sarcomata, but states that scirrhous, colloid, and melanotic tumors are unknown in this connection. Upon the question of scirrhus of the prostate, the latter authority differs from Thompson, who admits the existence of scirrhus of this organ, and states that he has himself seen one case, and knows of the existence of two others—one of them a case under the care of Mr. Adams, of the London Hospital.

Upon the question of colloid cancer of the prostate gland, the two authorities are agreed; but they differ as to the existence of melanotic cancer of this organ, for Thompson states that there are two cases of this affection on record.

[1] Thompson on Diseases of Prostate, p. 263.
[2] Op. cit., p. 264.
[3] Archives Générale de Médecine, 1869.
[4] Gross on Urinary Organs, p. 421.

A number of cases of malignant disease of the prostate gland can be found, which are reported as scirrhus, and these cases occur principally among the older writers; but this is explained by Jolly and Thompson by the fact that they based their diagnosis principally on the physical quality of hardness in the tumors, and did not rely on the more accurate and scientific test of a microscopical examination.

With reference to sarcomata of the prostate gland, Gross speaks of eight reported cases, and lays stress upon the fact that they occurred in infancy and early boyhood, and that the average age in the eight cases was only four years.

Socin[1] mentions a case of sarcoma of the prostate occurring in a man aged 51 years, who had been troubled with irritation of the bladder for more than a year, and had been compelled to use a catheter for five weeks previous to his death, which was caused by septicæmia; this case presents much similarity to that reported in this article.

A careful examination of the reported cases of malignant disease of the prostate will convince one that the encephaloid variety is the one most frequently met with, and I believe upon this point all observers are agreed. That childhood and old age are the periods of life in which it is most commonly found, is generally conceded, and Dr. Picard states that among children malignant disease involves the prostate more frequently than any other organ, the eye excepted.

Gross states that secondary deposits are found in ninety per cent. of all cases of this disease, but the extreme rarity of the involvement of the prostate itself, as a secondary affection, is also noted.

Spontaneous hemorrhage is also mentioned as a symptom of this affection, but is not as common as in carcinoma of the bladder, and is more apt to occur in the encephaloid than in the sarcomatous variety; indeed, it is said only to be observed in the sarcomatous tumors of the prostate after instrumental interference.

When the disease occurs in childhood, it runs a very rapid course, and generally terminates fatally in from three to nine months; whereas in adult and advanced age its duration varies from nine months to several years.

The treatment of malignant disease of the prostate is, of course, merely palliative. The pain and irritability referred to the bladder, must be relieved by full doses of opium, while retention of urine is to be treated by the cautious use of the catheter.

MEDICAL PROGRESS.

THE HYGIENIC, PHYSIOLOGICAL, AND THERAPEUTIC EFFECTS OF HIGH ALTITUDES.—DR. LOMBARD read a paper on this subject at the recent International Congress of Hygiene at Geneva, of which the following are the conclusions.

The insufficiency of oxygen in high altitudes may cause asphyxia if it is not combated by inhalation of oxygen; the *mal de montagne* is essentially caused by this diminution of oxygen. Respiration and circulation become more rapid as ascent is made above the sea level, while at the same time exhalation of carbonic acid is also augmented until an altitude of 1000 to 1500 metres is reached, when it commences to decrease. Above an altitude of 2000 metres, although respiration and circulation are accelerated, the insufficiency of oxygen tends to develop anæmia, although a temporary sojourn at such an altitude is stimulating to all the functions. The high altitudes exert a therapeutic and prophylactic influence on pulmonary phthisis. —*Gaz. Méd. de Paris*, September 30, 1882.

A NINETY-SIXTH PORRO-CÆSAREAN OPERATION.—DR. IGINIO TASINI, director and surgeon-in-chief of the Maggiore Hospital of Lodi, Italy, performed this operation in the said institution, on September 23, 1882. The woman was the subject of malacosteon, and her pelvis much deformed thereby. Both mother and child were saved. This is the 44th record of cure out of 96 cases. Italy numbers now 40 operations, with 17 women saved, or 42½ per cent. The whole percentage in the 96 cases, is 45⅝ of the mothers, and 77½ of the children.

RADICAL CURE OF HYDROCELE.—For this purpose, DR. LAMPUGNANI (*Gaz. Med. Lombardia*, 1882, No. 25), of the Pavia Hospital, employs with great success chloral hydrate dissolved in equal parts of warm distilled water, injecting, by means of Potain's capillary trocar, as a general rule, one or two grammes of chloral in children, four in the adult, and from that dose to eight grammes in the aged. The burning pain produced is allayed by cold applications; and if absorption has not become complete in eight or ten days, the injection, in a smaller dose, is repeated.—*Med. Times and Gazette*, October 21, 1882.

PERITONITIS IN NEWLY-BORN INFANTS.—DR. OSCAR SILVERMANN (*Deutsche Med. Zeit.*) writes that in newly-born infants two forms of peritonitis can be distinguished, a septic or acute, and a non-septic or chronic. The most frequent cause of the latter is syphilis. If the infants are not born dead, they show as symptoms, besides the aged and pinched expression of the face, prominent meteorism and ascites, enlargement of the spleen and liver, increased and shallow respiration, and cold extremities. A common result of this fatal peritonitis is atresia ani; less frequenlty stenosis and atresia of small intestines occur.

The post-mortem on the case here referred to, showed complete closure of the duodenum from the pyloric orifice to the opening of the ductus choledochus. The symptoms of a high-seated intestinal atresia, inflation of the abdomen to the navel, sinking in of the part below, distention of stomach, constant vomiting till death, and obstruction, were not present; but the abdominal distention being regular, the vomiting ceasing on the third day, passages of meconium and stools occurring, and tenderness of the abdomen also being present, the diagnosis of peritonitis was made.

The diagnosis of the septic form is easier, as it arises almost exclusively from infected navel wound. The symptoms are not, however, always constant even in this form, for vomiting and meteorism may be wanting, obstruction or diarrhœa present, and the exudation may sometimes not be felt on account of the meteorism.

The tenderness of the abdomen on pressure is not characteristic as it is also present in dyspepsia, colic, etc.; the pulse generally is frequent, but may be slow in weak newly-born infants, the temperature high, but may be subnormal. In the majority of cases there is jaundice, enlargement of the spleen, rapid emaciation and loss of body weight.—*Obstet. Gaz.*, October, 1882.

Detection of Bacilli in Tubercular Sputa.—Dr. Gibbes explains the failure to detect bacilli in undoubted tubercular sputa as follows: in some cases, where a patient is seen, and it is desirable to test the sputum at once, a small quantity only can be obtained, and this with evident effort; in these cases, no bacilli will often be found. The secretion coughed up comes from the back of the throat. A case of this kind puzzled him for some time. He had previously found a large number of bacilli, but on two occasions could find none. He gave the patient a wide-mouthed bottle, and told her to use it the first thing in the morning. She brought it the next day filled with thick sputum, which was literally crammed with bacilli.—*British Medical Journal*, October 21, 1882.

Oil of Wintergreen in the Treatment of Acute Rheumatism.—Dr. F. P. Kinnicutt draws the following conclusions from the results obtained in twelve cases of acute rheumatism, treated by oil of wintergreen.

1st. That in the oil of wintergreen we possess a most efficient salicylate in the treatment of acute rheumatism.

2d. That in its efficiency in controlling the pyrexia, the joint-pains, and the disease, it *at least* ranks with any of the salicyl compounds.

3d. That the best method of its administration is in frequently repeated doses, continued in diminished doses throughout the convalescence.

4th. That its use possesses the advantages of being unattended with the occasional toxic effects, the frequent gastric disturbance produced by the acid or its sodium salt, even when prepared from the oil of wintergreen; that its agreeable taste and finally its comparative cheapness are further recommendations in favor of its employment.—*Medical Record*, Nov. 4, 1882.

Ectrotic Treatment of Varioles in Smallpox.—Mr. M. D. Makuna draws the following conclusions in a paper in which he details his experience in the treatment of smallpox, in the Fulham Smallpox Hospital:

1. That ectrotics are useful only during the early stage of vesiculation.

2. That the cauterization by carbolic acid is the best of them all; but when a case has advanced in the vesicular stage some good might be done by cutting open the vesicles and applying a strong solution of carbolic acid.

3. That some good might be done by the caustic application of the nitrate of silver sticks to each vesicle after cutting them open, but the practice is attended with much pain and irritation.

4. That the practice of the exclusion of the ordinary daylight from the sick-rooms, especially at the expense of the ventilation must be condemned. (It does not prevent the process of germination, fermentation, or suppuration.)

5. That during the pustular stage our efforts ought to be solely directed to the evacuation of the contents of the varioles, relieve pain, and hasten the process of cicatrization.

6. That, during the convalescence, the less the irritants are used to remove the roughness and maculæ on the skin the better.—*Med. Press and Circular*, October 18, 1882.

Discoloration of the Skin by Topical Applications of Pyrogallic Acid.—Every one knows that when pyrogallic acid ointment is applied to the skin, the epidermis becomes more or less discolored, according to the particular part of the body to which it was applied, the tint varying from black on the palms of the hands and soles of the feet, to light yellowish-brown on other parts of the body. The color, which is confined to the epidermis, as several cases where desquamation has taken place have conclusively shown, is caused by oxidation, the oxidizing agents, according to C. Hupier (*Rép. de Pharm.*), being exceedingly numerous, the alkalies and the oxygen of the air playing the principal parts in the reaction.

The alkalies are to be sought for in the soap used to wash the patient's linen and person, more especially his hands. After having rubbed in the ointment, the patient generally has recourse to soap and water, in order to clean his hands, but he really increases the evil by oxidizing the pyrogallic acid absorbed by the pores of his palms. If he simply confined himself to washing his hands in warm water without soap and wiping them in a soft towel, the stain would be very much lighter. Another reason why the palms of the hands darken so considerably is the large number of sudatory glands that exist on these surfaces. Not only this, but the perspiration remaining alkaline until it is neutralized by the fatty acids secreted by the sebaceous follicles, it has an oxidizing action on the pyrogallic acid, there being no sebaceous follicles on the palms of the hands. Again, the epidermis being very thick on this part of the body, the color penetrates it to a greater depth. These last two remarks apply with equal force to the soles of the feet. Another reason why these parts become more strongly colored is that, pore for pore, a larger amount of perspiration is exuded.—*New Remedies*, November, 1882.

Case of Cancer of the Vermiform Appendix.—Dr. Beger reports a case of cancer of the vermiform appendix occurring in the clinic of Prof. Thiersch. The patient was a man aged 47, who had for three years suffered from a tumor in the right groin, which eventually suppurated and was opened by a free incision and a large quantity of pus removed. Although the general condition of the patient improved after the operation, a fistula with ulcerating edges remained. Microscopic examination proved the growth to be cancerous in nature, and from the glandular structure and freedom from symptoms of intestinal obstruction, it was concluded that the case was one of cancer of the vermiform appendix.

At the patient's request the cancerous appendix and a portion of the wall of the cæcum were excised under salicylic acid spray; death occurred in 36 hours.—*Berliner klin. Woch.*, October 9, 1882.

Diagnosis of Fœtal Monstrosities.—According to Prof. G. Calderini (*Deutsche Med. Zeit.*), there are no positive points for diagnosis of a malformed fœtus ante partum. It is, however, a point of great practical value as it would frequently change our entire method of delivery, if the viability or non-viability could be determined ante partum. The author calls attention to the following points, which should awake suspicion and direct our attention to the possibility of an existing malformation. He refers to the presence of an excessive quantity of liquor amnii. In three successive cases, he found such relationship existing between fœtal malformation and excessive liquor amnii. He supports his theory on the origin of the liquor amnii, for as it is supposed to mostly originate from the kidneys of the fœtus, an increased pressure in them must necessarily increase the waters. To prove this point changes in the vessels or heart must be shown to exist. In three cases out of four the writer found good grounds for the disturbed circulation, in the presence of only one umbilical vessel, a lengthening of the heart, pathological curvature of the spine, etc.

He hoped these remarks would lead to further ob-

servation of the relation existing between hydramnios and fœtal malformation.—*Obstet. Gaz.*, October, 1882.

CEREBRAL TUMOR AND UNILATERAL DEAFNESS.—STRUMPELL (*Neurolog. Centralbl.*, August 15, 1882) records a case of tumor of the right hemisphere, in which along with the general symptoms of cerebral tumor, and left hemiplegia with some degree of anæsthesia, deafness developed in the left ear, with a total inability to localize the origin of sounds.

After death a tumor was found of the size of an apple, situated in the middle of the ascending parietal convolution. Round the tumor the cerebral tissue was in a state of white softening, which extended forwards as far as the fissure of Rolando, backwards throughout the parietal lobe, and beneath almost into the central ganglia.

He is of the opinion that the deafness was probably due to lesion of the parietal lobe; and that the localization of sounds in space is a function of binauricular hearing.—*Brain*, October, 1882.

THE USE OF CARBONATE OF AMMONIUM SACHETS FOR BRONCHITIS.—M. MELSENS having observed the good effects of the atmosphere of a stable on those suffering from pulmonary diseases, which are rightly attributed to the emanations of carbonate of ammonium, he thought that continued, yet moderate, respiration of this salt might be useful in other affections of the respiratory organs. After a serious attack of bronchitis, he decided on trying on himself the effects of carrying a little bag round his neck containing little pieces of carbonate of ammonium. From the first day the amelioration was felt, and the cough soon disappeared entirely, while often persons who suffered from chronic bronchitis also obtained relief. The use of little bags of carbonate of ammonium are intended to produce the same result as the air of a stable or a gasworks.—*Med. Press and Circular*, October 18, 1882.

ANÆSTHESIA OF THE LARYNX PRODUCED BY CARBONIC ACID.—At a recent meeting of the Académie des Sciences, M. BROWN-SÉQUARD announced that some experiments had led him to believe that the sensibility of the pharyngeal and laryngeal mucous membrane might be so annulled by a stream of carbonic acid gas or chloroform, as to permit of the introduction of a laryngeal sound without causing any disagreeable sensations. His experiments have as yet been confined to animals, but as he proved as long ago as 1871 that a stream of carbonic acid might be directed into the pharynx without danger, it is possible that this method may become of use in laryngeal therapeutics. He promises to publish the results of the experiments with this object in view with which he is now engaged.—*Gaz. Hebdom. de Méd. et de Chirurg.*, October 6, 1882.

REGIONAL DIAGNOSIS AND TREPHINING.—WERNICKE and HAHN (*Virch. Archiv*, February, 1882) report a case of tubercular abscess of the left occipital region diagnosed from the symptoms, which were right hemiopia, proceeding to motor and sensory paralysis of the limbs on the right side. The skull was trephined (under antiseptic precautions) at the upper posterior angle of the left parietal bone, the dura and cortex incised and an abscess evacuated. The abscess was about the size of a hen's egg, and about three teaspoonfuls of pus were removed from it. The symptoms of paralysis and the general condition were at first greatly improved, but again returned before death, which took place a fortnight after the operation. The post-mortem examination showed a tubercular abscess in the left parietal and occipital region which had recently opened into the lateral ventricle. There were a few smaller softened tubercles in the neighborhood of the abscess. There were a few scattered patches of chronic tubercular pneumonia. The unsuccessful result was attributed to the unusual character of the abscess, and the absence of any capsule preventing the further extension and perforation into the ventricle.—*Brain*, October, 1882.

TWO NOVEL USES FOR PEPSIN.—DR. HOLLMANN (*Nederland Weekblatt*, 18, p. 272) has used an aqueous solution of sixteen grains of pepsin as an injection into the bladder of a patient who had hæmaturia, and in whom a catheter failed to empty the bladder. A few hours later, a dark, viscid, fetid fluid readily escaped through the catheter.

Dr. Ed. Rosenthal has used an acidulated and concentrated solution of pepsin as a local, hourly application to diphtheritic exudations of grave character, and reports that it caused rapid solution of the membrane. The solution was made with a drachm of Jensen's pepsin, twenty drops of chemically pure hydrochloric acid, in enough water to make a fluidounce.—*New Remedies*, November, 1882.

TABES DORSALIS IN INFANCY.—DR. LEUBUSCHER reports the case of a boy, aged three and a half years, who came under his care after having been unable to walk properly for six weeks; the difficulty being exaggerated when attempts at walking were made in the dark or with the eyes closed. There was some incoordination in the movements of the upper extremity and some defect of speech which appeared at about the same time that the difficulty in walking had been noticed. The knee and ankle reflex were absent, sensation appeared to be undisturbed, and no disease could be detected in any other organs. Marked improvement in the condition of the lower extremities took place under the use of the galvanic current, but speech and the condition of the arms remained unchanged. The question naturally arises whether this was an undoubted case of ataxia, the family history throwing no light on the case, or whether it was of diphtheritic origin, or evidences of the existence of a brain tumor; the author does not attempt to decide these points with positiveness.—*Berliner klin. Woch.*, No. 39, 1882.

SALICYLIC ACID AS AN ANTIPUTRESCENT.—The plan has been widely advocated of employing salicylic acid as a means of preventing decomposition in various forms of food. A committee recently appointed by the Académie de Médecine have been investigating the subject and publish their conclusions in the *Journal de Médecine de Paris* for October 14th. They declare that salicylic acid in quantities sufficient to prevent putrefaction cannot be regarded as anything but a poison, and all foods so contaminated should not be allowed to be sold.

TROPHIC TROUBLES IN NERVOUS DISEASES.—DR. POUGET gives the following *résumé* of his opinions as to the mode of production of certain trophic changes in nervous diseases, especially in locomotor ataxia. Falling of the nails occurs in locomotor ataxia without the existence of any traumatic cause; as a true trophic change it may occur in any stage of the disease and be accompanied by vaso-motor disturbances. The falling of the nail is generally preceded by an ecchymosis beneath the nail, but is unaccompanied by any pain, and, although the nail is rapidly reproduced, it is as rapidly lost again. This falling of the nail does not appear to be intimately connected with the shooting pains, the anæsthesia, or any special symptom of nervous disease.—*Rev. de Thérapeutique Méd. Chir.*, Oct. 15, 1882.

INTESTINAL MOVEMENTS IN DIARRHŒA.—Fifteen years have passed since Traube lamented that we had no definite experimental knowledge of the character of the intestinal movements in diarrhœa, and the recent series of experiments by PROFESSOR NOTHNAGEL, constitute the first attempt to supply the information. It is commonly assumed that during diarrhœa the peristaltic movements are increased in energy, and more constant than in normal circumstances. The experiments of Nothnagel were made upon the colon, as well as on the small intestine. The production of a moderate degree of inflammation proved a more difficult task than he had anticipated. The most suitable agent was a concentrated solution of chloride of sodium. Five c. c. of this were injected into the rectum several times in the course of twenty-four hours, the return from the anus being prevented. The movements of the bowel were observed the next day in the usual salt bath. Nothnagel, however, never succeeded in exciting inflammation in a larger tract than from thirty to sixty centimetres, and the enteritis was always slight in the upper, and considerable, and often hemorrhagic, in the lower part. The production of inflammation in the small intestine was much more difficult. Attempts to produce it by injecting irritant substances into the stomach by means of an œsophageal sound, and thus to imitate an occasional cause in man, were unsuccessful. Even sulphate of copper failed. Strong solutions caused rapid death, and weak solutions had no effect. Only local inflammation could be produced by the injection of a concentrated solution of chloride of sodium through the wall of a loop of the small intestine, withdrawn from the abdomen for the purpose through a small incision.

In both large and small intestine the peristaltic movements were rapidly increased by the inflammation, and the affected portion became filled with fluid, manifestly inflammatory exudation. The peristaltic contractions took the form partly of oscillatory movements, and partly of circular constrictions. Sometimes, however, the affected portion became the seat of a prolonged tonic contraction, which involved both the transverse and longitudinal muscular fibres. Very different, however, was the condition when twenty-four or forty-eight hours were allowed to elapse after the injection. The inflamed and empty section of the bowel was motionless, no contraction could be seen in it as long as the experiment lasted, and this even when the inflammation which had been excited was slight in degree. The conclusion therefore is that the early stage of inflammation is attended with very strong contractions in the inflamed portion, but that when the initial period is over and the inflamed part of the bowel is empty, the movement is not greater than in the normal bowel. Moreover, it appears that the contents of the bowel are, in the early stage, moved through the inflamed portion with increased rapidity.

In the course of his experiments Nothnagel had many opportunities of observing the occurrence of intussusception, which frequently resulted from a vigorous peristalsis in the uninjured intestine. The invagination always occurred from above downwards, a strongly contracted portion passing into a part in which the contraction was slighter, or which was at rest. The length of the intussusception was always slight—from half a centimetre to two centimetres. It usually quickly ceased, in consequence of the cessation of the contraction; and only once did it last as long as ten minutes. It is a frequent occurrence in the small intestine, but is comparatively rare in the colon. On one occasion an invagination of the colon was distinctly removed by the antiperistaltic contractions which were set up by an injection of chloride of sodium into the rectum.

Another subject investigated by Nothnagel is the influence of morphia on the intestinal movements. It will be remembered that he discovered in his earliest experiments that a sodic salt placed in contact with the outer surface of the intestine of a rabbit causes a local contraction which passes upwards. This effect was found to be prevented by a preceding subcutaneous injection of a small quantity of morphia, one to four centigrammes. Even bicarbonate of sodium, which under normal circumstances causes a very energetic contraction, no longer produces the effect. Nothnagel ascribes the effect to the stimulation of a nervous mechanism antagonistic to that which is excited by the sodic salt. If, however, a much larger quantity of morphia was injected—ten centigrammes, for instance—not only does the sodic salt produce its customary effect, but the constriction is much more energetic than under ordinary circumstances. This anomalous effect seems to indicate that, while small doses of morphia stimulate, larger doses paralyze the inhibitory nervous mechanism. Morphia appears thus to exert on the intestinal apparatus an action comparable to that which digitalis exercises on the innervation of the heart, which consists in a stimulation or paralysis of the inhibitory fibres of the vagus, according to the dose employed. Other experiments seem to show that the action of morphia on the intestine is exerted through the splanchnic nerves. The constipation produced by morphia is assumed to be the result of a stimulation of the inhibitory fibres contained in the nervous trunk, aided by a diminution in the intestinal secretion.—*Lancet*, October 21, 1882.

PATHOLOGY OF ADDISON'S DISEASE.—PROF. SEMMOLA regards Addison's disease as an affection of the central nervous system, the lesions of the suprarenal capsule being only manifestations of trophic changes. Prof. Semmola has recently published a memoir, in which he figures the actual histological changes observed in the spinal cord. These are, 1st, myxomatous degeneration of the stroma in certain points in the ganglionic centres and in the cœliac axis; and, 2d, œdematous infiltration of the tissues in the neighborhood of the medullary canal. The functions of the sympathetic are also disturbed, and, as a consequence, there are digestive diseases, fever, general disturbance of nutrition, and local changes in the skin. Prof. Semmola reports a case which is said to confirm his views as to the pathology of this disease, which was greatly benefited by prolonged galvanization of the sympathetic nerve by means of constant currents.—*Journ. de Méd. de Paris*, Oct. 14, 1882.

LIGATION OF PEDICLE AROUND DRAINAGE-TUBE IN EXTIRPATION OF THE WOMB.—DR. J. M. F. GASTON recommends the ligation of the pedicle around a metallic tube passed within the canal, through the cervix, or in the upper part of the vagina, when complete extirpation is requisite. It is claimed that the adoption of this process would have the following advantages:

1. Security against hemorrhage, primary or secondary, by the constriction of the tissues around the tube.
2. Efficient drainage and disinfection of the cavity.
3. Prevention of subsequent irritation by the removal of all ligatures before completing the cure of the case.
4. Maintaining the pedicle in its natural relation without any tension upon adjoining parts.
5. Closure of external incision by first intention, with the least possible delay.
6. Obviating the ordinary tendency to septicæmia.—*Medical and Surgical Reporter*, November 4, 1882.

INTESTINAL ORIGIN OF ALKALOIDS.—M. CH. BOUCHARD explains the presence of alkaloids in normal urine

by assuming that the alkaloids are formed in the intestine, absorbed by the bloodvessels, and eliminated by the urine. In support of this theory he states that fecal matter both in health and disease contains alkaloids in much larger quantity than he has been able to detect in the urine. He believes that the quantity of these alkaloids depends upon the activity of intestinal fermentations. The urinary alkaloids have the same chemical properties as those found in the feces, and their quantity varies with the amounts present in the intestinal contents.—*Rev. de Méd.*, Oct. 10, 1882.

Mechanical Stimulation of the Brain.—Various opinions have been expressed regarding the degree to which the cortex cerebri is excitable by mechanical agencies. Few experimenters have found the mechanical excitability to be well marked. The most noteworthy results thus obtained are those of M. Couty, who described movements as produced by such stimulation of the motor region, the effect closely resembling that following electrical stimulation. He stated, also, that these movements could be increased by causing inflammation in the cortex, either by exposing it to the air for a certain time, or by the action of various irritant substances. The nervous tissue becomes a little more consistent in consequence of the inflammation, and is less easily reduced to a soft pulp by mechanical disturbance. The effects obtained by M. Couty were of two orders: movements first on the opposite side of the body; and, secondly, on the same side as the hemisphere irritated, and in certain cases movements more or less general were produced. The first of these alone are comparable to the results of electrical stimulation of the motor zone, the others must be regarded as of the nature of reflex actions—*i. e.*, of sensori-motor nature. M. Vulpian has recently made a large number of experiments to ascertain the degree and character of the mechanical excitability of the gray cortex of the brain. In mammals, dog, cat, and rabbit, in the normal condition, he could never produce in this way the slightest movement either in the limbs of the opposite side, or in those of the same side. The mechanical stimulation was produced by rubbing the surface of the cortex with a small sponge, or a fragment of amadou, or with the points of dissection-forceps. Thus, in the dog and cat, after having carefully ascertained the points in which electrical stimulation produced movement of the face, or of the fore limb, or of the hind limb, varied mechanical stimulation was applied to the same points, but no movement could in any case be perceived. If therefore movements resulted from such stimulation in the experiments of Couty, the effect must have been purely accidental, or the consequence of some experimental error. The results were also negative when Vulpian repeated the experiments, after having produced inflammation of the surface of the sigmoid gyrus by tincture of cantharides, by essence of mustard, or by nicotine. The stimulation of the inflamed surface by various mechanical agents did not cause the slightest movement in any part of the body. Nevertheless, in Vulpian's experiments, certain effects were observed analogous to those which Couty regards as reflex, and which are produced by the mechanical excitation, not of the motor functions of the cortex, but of the sensory regions. When the sigmoid gyrus of the dog is galvanized or faradized, a certain amount of pain is produced even when the electrodes are placed a long way from the shreds of the dura mater, which are extremely sensitive. The points in this region which seem to be the most sensitive are those in which stimulation causes movement of the fore or hind limb on the opposite side, although these are far less sensitive than is the dura mater. But mechanical stimulation of these regions never, in Vulpian's experiments, caused indications of pain. Nevertheless, similar excitation of the deeper layers of the cortex, or in the subcortical portion of the white substance, usually caused unequivocal signs of suffering. When metallic wires are passed into the motor points of the sigmoid gyrus, and a faradic current of moderate intensity is passed through them, the movements caused in the limbs on the opposite side become stronger the deeper the wires are plunged into the cerebral substance, provided they penetrate to the white substance. These movements are absolutely the same as those which are produced by faradization of the surface of the convolution, and differ only in their greater extent and greater energy. In the same way, the pain becomes more intense when the wires reach the white substance. Thus the sensibility of the cerebrum itself is incontestably low. It is, however, augmented by repetition of the stimulus, and thus it is possible that pathological irritation may cause an exalted sensibility, which is evidenced by pain. It is only in the white substance beneath the sigmoid gyrus that mechanical stimuli elicit any evidence of sensibility. Elsewhere the white substance of the cerebral lobes seems to be absolutely insensible, although on this point M. Vulpian's experiments are not sufficiently numerous to enable him to speak with perfect confidence.—*Lancet*, Sept. 16, 1882.

Fatty Embolism in Fractures.—Dr. Angelo Minich (*Lo Sperimentale*, March and April, 1882) has recently published a valuable monograph on this subject, of which the following are the conclusions based on his personal experience:

1. Fatty embolism occurs in all cases of fracture, except in children, where it is absent on account of the small amount of fat contained in the skeleton.
2. This accident frequently causes death or alarming symptoms.
3. In such cases the fat does not cause inflammation, infection, or pyæmia.
4. Death is caused by enfeeblement of the central nervous system.
5. The presence of free fat, or fat in the form of an emulsion in the urine, is frequently a sign of dangerous embolism.
6. In cases of death after fracture, a diagnosis of fatty embolism should only be made with great reserve.
7. The treatment can be only symptomatic, and is generally powerless to prevent death in grave cases.—*Rev. de Chirurg.*, October 10, 1882.

To Disguise the Odor of Iodoform.—Dr. O. Petersen recommends the addition of one drop of the tincture of musk to each 40 grains of iodoform solution.—*Med.-Chirurg. Centralb.*, Sept. 29, 1882.

Cæsarean Section.—A successful case of Cæsarean section is reported in the *Archiv für Gynæcologie*, xix. 3, by Dr. Leopold, of Leipzig. The patient was a woman 29 years of age, who had already borne one child, extracted by cephalotripsy after perforation. She was 125 ctm. in height, and had a universally contracted rachitic pelvis of a flattened ace-of-hearts form. The conjugate diameter was 6 ctm. The operation was performed under antiseptic precautions. Previous to opening the uterus, the serous membrane was dissected off a longitudinal elliptical space, and turned back, after which a melon-like slice of uterus was removed. This procedure was with the object of getting sufficient serous membrane to allow of its edges being turned down previous to the application of the sutures. At the end of the third week both mother and child were convalescent.—*Med. Press and Circular*, October 18, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, NOVEMBER 11, 1882.

THE THEORIES OF THE MERCURIAL TREATMENT OF SYPHILIS.

WHILE it may be admitted that the clinical evidence in favor of the administration of mercury in the treatment of certain stages of syphilis is quite sufficient to warrant its invariable employment, it is, of course, important to understand, if possible, its *modus operandi*.

The only theories pretending to explain its antisyphilitic properties, and at all worthy of consideration, may be classed under three heads: First. That it has an antidotal action by virtue of which it destroys the virus of the disease. Second. That through its so-called "tonic" properties it counteracts the anæmic tendencies of syphilis, and by improving the condition of the blood diminishes the severity of the attack. Third. That by promoting fatty degeneration and destructive metamorphosis it favors the disintegration and absorption of the new cellular elements which are found to pervade the tissues during the secondary period.

The first of these theories is alike incapable of complete refutation or of satisfactory demonstration. The existence of a virus has been denied, and has certainly never been proved. It is always imaginable as a more or less immaterial and elusive agency superadded to the demonstrable accompaniments of the disease, at one time infecting every portion of the organism, at another becoming dormant or quiescent for long periods, and then again breaking out with renewed vigor and virulence. It is certainly not a satisfactory theory which depends upon this mysterious agency and an equally mysterious destruction of it to account for the beneficial effects of mercury in syphilis, and it would only be acceptable in the absence of one more rational or better founded.

The facts that in the secondary stage the number of the red-blood corpuscles is markedly diminished and that under the use of mercurials it almost invariably increases, are well established by clinical and experimental observations. Is this, however, conclusive evidence of the possession of "tonic" properties on the part of the drug? If so, and if upon these properties its usefulness is contingent, why do not other tonics, especially iron, exercise an equal or at least a similar effect in the control of symptoms? That they do not is familiar to every syphilographer of experience, who, using them frequently as adjuvants, would not think of relying upon them exclusively.

As regards the last of these theories, two undeniable statements are made, viz.: that throughout the entire course of syphilis, and especially during the secondary period, extensive cell exudation and proliferation occur in all the tissues known to be affected by the disease, and probably in others beyond the reach of immediate exploration, and that the symptoms of syphilis are almost without exception produced in this manner. And next that mercury is in this, as in all other cases where it is desirable to prevent the migration and multiplication of new cell elements, or, especially, to favor the absorption and delay the organization of those already formed, by far the most potent drug in our armamentarium.

It is for this reason that we give it in meningeal troubles, in joint diseases, in pleuritic affections, in glandular enlargements, etc., and it is for the same reason, say the advocates of this theory, that it does good in syphilis. The anæmia of syphilis is explained by them as resulting from the impression made on the white-blood corpuscles by the newly formed and immature cells so abundant throughout the tissues, causing an arrest in the development of the former, prior to their transformation into red-blood-globules. The apparent tonic effect of mercury would thus seem to be due indirectly to its action on these new cells, which it would most readily influence by reason of their very instability. By favoring their elimination it would of course favor the uninterrupted manufacture of red-blood cells, which would increase in number.

The action of the drug in the later or tertiary stages of the disease is thought to depend on similar causes, but its therapeutic effects are then inferior to those of iodide of potassium, with which, however, it may be advantageously combined in the majority of instances.

Here again diverse opinions exist as to the *rationale* of the action of the iodides, and on some

future occasion it will be worth while to allude to and endeavor to elucidate them.

THE NATIONAL BOARD OF HEALTH.

From the full report of the proceedings of the American Public Health Association, and the letter of our Indianapolis correspondent, which are given in our last number, it is evident that the sanitarians of the country are almost unanimous in condemning the action of Congress in cutting down the appropriations for the National Board of Health, and also that they are upon the whole well satisfied with its organization and the character and amount of work which it has accomplished. This opinion is, we think, shared by the great majority of physicians in this country, and, in view of this prevailing sentiment, it is difficult to understand the motives which governed Congress in its attempt to asphyxiate, without totally destroying, the Board.

The statements of Dr. Cabell, the President of the Board, and of Dr. Bailhache, the representative of the Marine-Hospital Service, throw some light on this matter. It appears that the Treasury Department is hostile to the Board, claiming that it should have control of the disbursement of all funds appropriated by Congress for quarantine purposes, and preferring its own medical officer, the chief of the Marine-Hospital Service, as its agent for such work. The Marine-Hospital Service appears to be desirous of having the control of all quarantine work, claiming that it can perform this service at least as well as the Board, if not better, and with less expense. In this connection, the sixth resolution passed by the Association is especially significant, viz.:

"*Resolved*, That so long as the United States Government confines its maritime and inland quarantine service to the aiding of State and local boards of health, it is essential for the best results that such aid shall be through channels most generally acceptable to State and local boards of health whose coöperation is requisite, and we sincerely belive that the National Board of Health is the channel most generally acceptable."

The truth of this proposition seems indisputable.

We must confess that it has always seemed to us an unfortunate thing that quarantine duties and responsibilities should have been placed on the National Board in the first years of its existence—at all events so far as these involved executive functions. That the Board has done good work in securing comparative uniformity and simplicity in local quarantine regulations, we freely admit, and its influence in favor of proper inspection, disinfection, and prompt return to commerce of infected vessels, instead of the old style of detention for a month or more, has certainly been most beneficial. It is not clear to us, however, that it might not have effected all this equally well under the provisions of the Act creating the Board, which confined its work in regard to quarantine to the preparing a report on the subject.

The great value and importance of a national health organization depends upon its having the power and means to collect and diffuse information—to investigate the causes of disease, to educate the public, to furnish reliable data as to the sanitary condition of various places, and to bring to bear upon indolent and inefficient authorities the pressure of an enlightened public opinion. The work of the greatest permanent value which the Board has thus far done, has been in this direction; and yet it is precisely this class of work which the last House of Representatives selected for condemnation.

Putting aside the charges of extravagance made against the Board on the floor of the House—charges which we may consider hereafter—what were the reasons given for limiting the Board to work connected with cholera, yellow fever, and smallpox—*i. e.*, to quarantine, and to refusing to allow it to make investigations into the causes of diphtheria, or typhoid, or to publish its bulletin? On consulting the *Record*, we find that Mr. S. S. Cox, of New York, said: "I deny the right of the Federal Government to investigate the causes of disease. It has no more right to investigate smallpox than it has to investigate chickenpox or the measles." Mr. Robeson, of New Jersey, said: "We have confined the investigation to yellow fever and cholera, because the germs of these diseases are unknown, and because the specifics which are to meet and destroy them are yet undiscovered." Such are the views of two of the leaders of the House, displaying a depth of self-satisfied ignorance which we hope is not common among the members; for, if it is, there is small prospect of wise legislation on this matter.

With regard to the attitude of the Marine-Hospital Service in this matter, it does not seem to us to be quite satisfactory. It has the charge of the sick seamen and boatmen of the commercial marine, and has about $400,000 annually to expend for this purpose, besides special grants from Congress for the construction of hospitals. So far as we can learn, it has no more officers than are necessary to do this work; and it would seem as if it had plenty to do. Under the circumstances, the hostility of the Service to the National Board, and the openly avowed desire of its chief and representative to obtain control of quarantine, seem to us to be at least in bad taste, and not well calculated to attain its object. It would be much better for the Marine-Hospital Service to so manage the work with which

it is now charged, that there shall be a desire on the part of others to increase its field of action, and to wait for others to ask for the transfer of quarantine authority from the Board to it, rather than go into the lobby and urge such transfer itself.

It is the duty of the medical men of the country to look into this matter, and to endeavor to instruct their representatives in Congress so that such absurd utterances as those of Mr. Cox and Mr. Robeson will be estimated at their true value. On one point we think all physicians and scientific men can agree, viz., that the conjoint recommendation of the Board and the Academy of Sciences, made in 1879, that the United States should appropriate $30,000 per annum for skilled investigations into the causes of disease, and for sanitary surveys, was a wise one, and should be carried out, no matter who is to have charge of quarantine, or whether the United States is to interfere with quarantine at all.

SEWER GAS.

DR. F. H. HAMILTON, in the *Popular Science Monthly* for November, gives a rather pessimistic paper on sewer gas, taking the ground that it is the means of conveying scarlatina, typhoid, diphtheria, etc., and is the cause of much of the excessive mortality in cities; that all house plumbing is more or less defective, that water-traps will exclude neither gases nor germs, and that the only way to obtain safety is to exclude from those parts of the house in which we live, all plumbing having any direct or indirect communication with the sewers; in other words, that such plumbing shall be placed in a separate building or annex.

In this journal for September 2d, we gave a paper by Prof. Jos. G. Richardson, in which he argued that "the various theories to account for sewer infection in spite of air-tight traps, such as the siphoning out of traps, their partial corrosion and leakage, the absorption of sewer gas by the fluid sealing them, and its evolution from the inner or house surface, etc., may be relinquished," his reason being that a layer of micrococcus and mycelium may creep along the interior surface of a trap from the sewer to the house side and there give off its germs.

If these gentlemen are right, the residents of large cities are in a very dangerous position, and the only remedy suggested is either to build an annex for our plumbing, which in most cases is simply impossible, or to undertake to secure systematic and constant disinfection of all pipes, traps, etc., for which purpose there are various patent contrivances, the proprietors of which no doubt will extensively advertise the views above mentioned. Is it true, however, that the gases in a system of properly constructed sewers and connections are so very deadly? Is it true that the plan of house drainage which is now approved and recommended by the leading sanitarians and sanitary engineers of England and this country affords little or no protection against sewer gases or germs?

To the best of our knowledge and belief the answer to both these questions must be negative, and in this we agree with the immense majority of skilled engineers and scientific men who have investigated the subject.

Experience has shown that sewered cities are healthier than those which are not sewered, and that in cities partially sewered the mortality is less in those portions provided with sewers. This is notably the case in the city of Chicago. It is also found that diphtheria and typhoid fever are more prevalent in unsewered cities. The gases of sewers do not cause any specific disease, and are rendered harmless by sufficient dilution which may be secured by ventilation of soil-pipes and sewers. In a properly constructed system of sewers and house-connections there will be little or no offensive odor in the sewers. The great point to be kept in view in such a system is that all excreta shall be promptly and entirely swept out by a sufficient current of water. This cannot be done when sewers receive overflow-pipes from cesspools, for the discharge from these will always be more or less offensive.

In a proper system the communication between the sewer and the house soil-pipe is entirely cut off by means of a trap in the house drain outside the house, with an opening from the external air into this drain on the house side of the trap. The soil pipe is also continued up full size through the roof and left freely open at the top. With such an arrangement there is no danger of the passage of gases from the sewer to the house. The real danger is from minute particulate germs, and the practical question is, Can these pass a good ordinary water-seal trap? The experiments of Carmichael, Wernich, and Pumpelly show that they cannot, and so far as we know there is no record of any experiment to show the contrary. The test is not difficult of application—and until some competent observer obtains results different from those reported by the above-named gentlemen, we are bound to accept them. The fact reported by Dr. Richardson does not seem to have any bearing on this question. He found a fungous growth in a ball trap. But a ball trap is not recommended by the best authorities, and Dr. Richardson's observation simply confirms the unfavorable opinion we have long had of such contrivances. Nor does the Doctor present any evidence that the growth started from the sewer side of the trap. It seems quite as likely that it started from the house side. Again the character

of this growth is entirely different from that which characterizes the development of those microzymes which are capable of causing disease. It consists of creeping threads having a certain amount of consistency and firmness, whereas the germs which we know anything about are minute particles or single cells. The experiments of Prof. Doremus, to which Dr. Hamilton refers as proving the passage of gases through water traps, have really no bearing on the question under discussion. Prof. Doremus used the pure gases in a totally unventilated pipe—the actual state of things is a very dilute gas in a well-ventilated pipe—and under such circumstances Carmichael demonstrated by repeated experiments that the amount of ammonia passing through such a trap in twenty-four hours was from $\frac{1}{400}$ to $\frac{1}{200}$ of a grain, and that the amount of sulphuretted hydrogen passed in the same time is $\frac{1}{100}$ of a grain. These amounts cannot be appreciated by the sense of smell, and would have no effect on health were they one hundred times greater.

But, say the alarmists, your traps may be siphoned out. So they may if not ventilated—we are not defending a patent trap, or the usual contract job of plumbing; we agree that house drainage should be much more carefully looked after than it usually is, but the methods of securing a trap against siphonage have now been made clear by the experiments of Messrs. Bowditch and Philbrick published in the *Sanitary Engineer*.

In short, it seems to us that it is not yet demonstrated that it is necessary to fit up every wash-bowl, bath-tub, and water-closet with a complicated germicide apparatus, nor to build an annex to contain our house drainage, and we would advise our friends to make use of the best modern appliances, improve them if they can, but not try to frighten the public into hostility to house drainage and sewage, nor deny the results obtained by careful, well-known scientific observers, without having made a few experiments of the same kind themselves.

ASEPTIC VIRUS.

If some method could be discovered by which all extraneous qualities could be eliminated from vaccine virus so that only the really pure and isolated virus of vaccinia remained, one of the most formidable obstructions to the progress of universal vaccination and the extinction of smallpox would be overcome. The reports from various parts of the country, during the recent prevalence of smallpox, of well-authenticated cases of vaccination attended by very serious results from the inoculation of septic matter, and the consequent discredit of this valued means of prophylaxis, are suggestive of the need of renewed efforts in this promising and not altogether novel field of enquiry.

Three years ago Köhler experimented with thymolized lymph (one part of lymph and two parts of thymol solution, 1:1000) with such success as to warrant its use in the vaccine institution at Halle ever since. More recently, Dr. Richard Pott has ventured upon the use of other antiseptic agents, such as salicylic acid, boracic acid, and carbolic acid, with, as he claims, commendable success. Whether or not a solution sufficiently strong to neutralize all foreign and accidental admixtures will not also render inert the vaccine virus itself, is a question which needs further investigation. A five per cent. solution of carbolic acid had this effect.

The advantages claimed for the aseptic lymph are the following:

1. Any erysipelatous virus in the vaccine is probably destroyed.

2. Aseptic lymph may be preserved in good condition for years.

3. It is thinner, contains no fibrinous coagula, and with it twice as many children may be vaccinated as with the undiluted lymph—a circumstance of some importance in the present large demand for vaccine.

THE TREATMENT OF TYPHOID BY ERGOT.

Amongst the novelties of medical practice with which we are now surfeited, is the proposed employment of ergot in the treatment of typhoid. The results of this practice amply justify its introduction if we may rely on the published evidence. M. Débove administers in certain cases of typhoid one gramme (15½ grs.) of ergot in two doses. Of 24 cases, 8 were very grave, 11 were serious, and 5 were of moderate severity, and of these but one proved fatal. In a former series of 6 cases, 1 was very grave and 5 were of moderate severity, and all recovered. In still another series of 6 cases, 3 being very grave, 2 serious, and 1 of moderate severity, all recovered but one.

There is no explanation of the period and manner of exhibiting the remedy given by M. Débove in his report to the Academy of Medicine. As the whole amount of fifteen grains is given in two doses, we may assume that one is exhibited on each of two days of the first week.

Our esteemed colleague, Dr. Seguin, has been visited with a calamity than which none greater can befall any man. In the presence of such an affliction, words are powerless to convey an adequate sympathy. We content ourselves, therefore, with the simple assurance that we, as well as others of his numerous friends, are not unmindful of his sufferings, and share as far as we may the anguish of his bereavement.

REVIEWS.

Two Hard Cases: Sketches from a Physician's Portfolio. By W. W. Godding, M.D., Washington, D. C. Pp. 257. Boston: Houghton, Mifflin & Co., 1882.

Of the two hard cases the subjects of these essays, one was an inmate of the Taunton Asylum, Mass., and the other was Guiteau. The author, Dr. Godding, is an asylum superintendent. He comes forward with two cases to illustrate the position that mere eccentricity and faulty education make insanity. According to this view, half mankind should be shut up in an asylum to end the miserable sham by suicide, as was the final destiny of hard case No. 1. It would require a nice exhibition of casuistic skill to determine whether this hard case owed his final step to an irresistible impulse or to the horrible tedium of asylum restraint. He committed suicide after several escapes, and on his last return—it appears to us—in sheer desperation. What must be the future of a youth who has spent many years in an insane asylum? What hope for employment? That Dr. Godding's No. 1 should, in absolute despair, have returned to the asylum to commit suicide, seems to us a perfectly suitable conclusion to such a life.

The second "hard case," Guiteau, was, according to Dr. Godding, insane, and had always been so. Every act of his life, from his youth up, is a proof of mental perversion. He was not merely an eccentric, a deadbeat, an imposter, but insane. Our author does not define the form of mental derangement of which this criminal is the victim. He probably takes shelter behind the convenient *primäre verrücktheit*, which has rendered so much service to a certain group of mental philosophers.

The book is written in a popular tone, and is rather intended for literary and general than medical readers. It is very pleasant reading. Dr. Godding has a trained literary faculty, and hence his effort partakes more of the sensational than of the scientific. With this limitation we can commend it to our readers as an interesting book.

The Surgical Treatment of Hemorrhoids. By Walter Whitehead. Reprint from the *British Medical Journal*. 8vo. pp. 15. London: J. & A. Churchill, 1882.

Mr. Whitehead proposes to abandon the ligature and return to the knife, to seize each hemorrhoid by forceps, isolate it, or each separate lobe, if it be composite, and dissect it out by a V-shaped incision, twisting any arteries that bleed and uniting the margins of the mucous membrane by sutures.

In spite of the cases given, the method we fear is full of danger from hemorrhage and possible cicatricial stricture, but the scriptural rule is good, "Prove all things, hold fast to that which is good." His directions as to rest for three days previous to any such operation, in order to reduce the piles to their smallest size, his suggestions as to diet, to cleaning out the rectum, dilating the sphincter etc., are judicious.

Nitro-glycerine in Angina Pectoris. By William Murrell, M.D., M.R.C.P., etc. Pp. 78. Detroit, Michigan: Geo. S. Davis, 1882.

This libellus is an interesting account of Dr. Murrell's study physiologically and therapeutically of nitro-glycerine. We owe chiefly to the author our present knowledge of the action of this substance, although it had been investigated to some extent before he undertook the study of its actions.

Our readers will, doubtless, remember that we commented on the properties of this agent some time ago, and indicated Dr. Murrell's share in reducing the existing information into exact order, and in establishing its therapeutical uses.

This brochure is a nicely arranged book, from which the reader can obtain full information on this interesting remedy.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 2, 1882.

Fordyce Barker, M.D., LL.D., President, in the Chair.

After the reading of the report of the previous meeting by the Secretary, the deaths of the non-resident Fellow, Dr. J. Foster Jenkins, of Yonkers, and of the Corresponding Fellow, Dr. James C. Townsend, were announced.

The scientific work of the evening consisted in a paper by Dr. W. Edward Forrest, entitled

TREATMENT OF LABOR, WITH REFERENCE TO THE PREVENTION OF SUBSEQUENT UTERINE DISEASE.

Dr. Forrest having been summoned by telegram to the bed-side of his sick father, his paper was read by the Secretary of the Academy, Dr. Katzenbach, an abstract of which is as follows:

There is an unquestionable relation of cause and effect between the puerperal state and many cases of uterine disease. Gynæcologists tell us that from one-third to one-half of the cases of this disease that come under treatment date their trouble from a previous confinement. If such be true, and we have no reason to doubt the statement, it behooves us as obstetricians to look into this matter closely and see if the responsibility rests in any degree upon us. When we consider how chronic, how costly, and how injurious to mind and body uterine diseases are, we must realize that the prevention of this curse of the female sex is worthy our profoundest study and our greatest care. *Dr. Forrest did not wish to be understood as considering the obstetrician's responsibility for all the diseases of the uterus that follow the puerperal state, but there could be no question that some of the causes might be prevented by an intelligent and scientific management of labor.* We must sometimes feel that, had obstetricians made as great advances in *preventing* diseases as gynæcologists have in curing them, they would be less prevalent. The author stated that it would be his aim, first, to make his remarks practical; and, second, to found his statements as far as possible on anatomical and physiological facts.

Uterine disease, as a sequel of labor, may arise from two general conditions: First, from laceration of the pelvic tissues; and, second, from subinvolution of the uterus and vagina either with or without laceration.

Laceration, as a cause, is first in time as well as in importance. Indeed, subinvolution, as a rule, can be traced to laceration. Hence, it is of the utmost importance to study the manner in which lacerations are produced, and the means by which they may be avoided or remedied.

As to the frequency of laceration of the cervix, Dr. Emmet found that of all the women coming under his treatment for uterine disease, one-third were suffering from laceration of the cervix

Tables furnished by Dr. Sinclair, of the Boston Lying-in-Asylum, that out of 216 women examined by him,

on an average of 16 days after confinement, 76 or over 30 per cent. had laceration of the cervix, of these 44 were primiparæ and 32 multiparæ, 76 had fissure of the cervix, while 44 had well-marked or deep laceration. Of these, only 3 were forceps cases. From the above statistics it was plain that laceration of the cervix is a common accident during labor. Its frequency had not been suspected because physicians, as a rule, had not been in the habit of examining patients carefully at the close of the puerperal period, say 12 to 20 days after labor.

Not all the women with laceration of the cervix suffer from apparent uterine disease, but, as already stated, a large percentage of such diseases spring from laceration.

The most common cause of laceration spoken of in our text-books is rapid labor, or a rapid first stage of labor. Emmet says: "From *a priori* inferences I was prepared to learn that rapid labor was the most common cause of laceration of the cervix." Dr. Forrest, however, was of the opinion that this was the least common of all the causes of laceration. In support of this opinion he stated that dilatation is usually spoken of as if it were principally due to the mechanical pressure of the head or membranes upon the cervix. From this conception would arise a second theory, as a corollary to the first, namely, if the head descends slowly, the os will be less likely to be torn. Now, these two theories are directly contrary to the facts. Statistics show that only four per cent. of lacerations are characterized by rapid first stage of labor, while over thirty per cent. are marked by tedious first stage. In explanation of this fact it was stated that dilatation is not a mechanical but a physiological process. It might be called relaxation rather than dilatation. If dilatation were due to pressure alone, or mainly, why, in one case, should a thin cervix resist for hours hard pains and great pressure without dilating, while in any other case the os might dilate in a few minutes almost without pain. The author had had two cases where the os must have dilated, or rather relaxed, while the women were asleep, so that the children were born immediately upon the awakening of the mother, and with a single pain. He had observed the os dilate from the size of a silver dollar to full dilatation with a single pain, yet without laceration. Among uncivilized people rapid and unexhausting labor is the rule.

From these facts we may infer that normal dilatation of the os is rather a physiological than a mechanical process. The preparation for this process commences weeks before labor. We might infer that in natural labor there is not a contest between the body of the uterus and the cervix; but that there is harmony of action between them, so that when contraction commences in the fundus, relaxation takes place in the cervix. It was only when perverted nerve-force disturbed this harmony of action that mechanical dilatation of the os became an important factor. Reil nearly eighty years ago enunciated this theory, ... t during pregnancy the uterine polarity resided in the cervix, and that at the commencement of labor the polarity leaves the cervix and resides at the fundus, and that rhythmical contraction above then goes on, with relaxation below. This theory explains the statistics of Dr. Sinclair already referred to, in which of 76 lacerations, only 3 were characterized by rapid first stage of labor; that is, a first stage less than three hours in length. We can now understand why a rapid labor so seldom causes laceration of the cervix. First, rapid labors, as a rule, are natural and have undisturbed nerve relations; second, there may be no more pressure on the cervix than in tedious labor, because the cervix in the former case gives way before the advancing head; third, in the rapid labor the resiliency of the cervix is not exhausted by long-continued pressure, and therefore pressure is less likely to cause laceration. But suppose that precipitate labor does threaten laceration. The theory above given indicates the remedy, viz., the administration of something that controls perverted nerve force; hence, chloroform, chloral, or morphia. The finger of the attendant on the child's head will modify undue pressure on the cervix.

The second cause mentioned in our text-books is tedious labor, or, rather, a tedious first stage of labor. This is spoken of as a possible cause rather than a most important one. Dr. Sinclair's tables show that of 37 well-marked cases, 34 were characterized by a first stage of labor lasting from 12 to 36 hours. Dr. Emmet had found that 30 per cent. of the cases treated by him were attributed to tedious labor, which was opposed to his *à priori* inferences. This proportion would be greatly increased by the addition of forceps cases which could be placed under the head of tedious labor.

It seemed evident, then, that tedious labor is a very prolific cause of laceration of the cervix. Anatomical reasons in support of this view were then adduced by the author of the paper. Copies of Braun's plates, made from frozen sections, were presented, showing the relation of the pelvic contents in the ninth month of pregnancy and at the beginning of the second stage of labor. It was pointed out that the change which had taken place in the first instance was that the bladder occupied a position behind the pelvis. The os internum and os externum were on a line with the pelvis and that there was a solid pelvic floor. In the second instance it was shown that the os internum had now risen some distance above the pelvis. The bladder had likewise been drawn upward and the urethra lengthened. The walls of the uterine body have become shorter and much thicker, while the cervix, on the other hand, has become long and very thin. In this case the os internum had dilated in *harmony* with the dilatation and retraction of the os internum, and the parturient canal was ready for the speedy delivery of the child.

In the case of tedious labor, when the os externum does not dilate in harmony with the os internum it was shown that as labor goes on hour after hour, the uterine body will shorten, the os internum and bladder will be drawn upwards by the shortening from one to three inches above the pelvis, and that as the os externum does not dilate the shortening of the uterus and the retraction of the internum must take place at the expense of the cervix which becomes stretched to three or four inches in length and as thin as parchment. This could be easily demonstrated upon a living patient. If an examination of a case of tedious labor was made where the delay was in the first stage, it would be found after some hours that the bladder, even if it contained bu an ounce of urine, would present itself as a bulging tumor halfway to the umbilicus, and upon passage o the catheter the urethra would be found three inches in length.

What then was the remedy for this prolific cause of laceration of the cervix? evidently the prevention of tedious labor. This was to be accomplished by restoring, if possible, the harmony of action that should exist between the body and the cervix uteri, so that dilatation below may keep pace with contraction above. The remedies to be used in the shape of drugs were morphia and chloral, which were to be given, not as commonly supposed, for their relaxing effect on the cervix, but for the purpose of relaxing disturbed nerve function. They should be administered before nerve force had become exhausted. They were to be administered in moderate doses, for the object was not to paralyze the uterus but to regulate nerve action. Gentle manual dilatation of the os was recommended as a useful measure.

The indication for action will be found from a study of the position of the bladder by observing when the utero-cervical junction begins to appear above the pelvis, showing that the os internum has dilated, and what is of more practical importance than either of these signs, by watching the formation of what Dr. Forrest calls the anterior vaginal cul-de-sac, which is formed between the pelvis and the cervix by the rising of the bladder.

Why should one woman with a normal pelvis and the child in a favorable position suffer for hours before the os dilates, while another woman, whose structure is apparently the same, or even a weaker muscular development spend about an hour in the first stage. This question could not be easily answered, but the process was probably governed by nervous conditions, the laws of which we have not yet fathomed.

Instrumental delivery was often spoken of as a cause of laceration of the cervix; undoubtedly, the forceps in careless and unskilful hands may give rise to this accident, but it has been shown that tedious labor is a common cause, and it is in just such cases that the forceps is used. It is impossible to say how many lacerations are directly due to the forceps. The truth is, that the forceps when carefully used seldom cause laceration.

When the profession are united in a uniform system of observation, we would have a ground on which to make some positive deductions.

Digital dilatation is spoken of as a frequent cause of laceration of the cervix, but the author was convinced that, when intelligently employed, it would not only not cause laceration, but might be a most important means of preventing it. The time for this measure is when the evidences are present to show that the os externum is not acting in harmony with the lower uterine zone.

Abnormal presentation may be one of the causes of laceration of the cervix, but it is hardly within our province to speak of it here.

Premature rupture of the membranes, if it occurs spontaneously, may predispose to such an issue. It is hardly necessary to caution against intentional rupture of the membranes until the os was dilated.

The giving of ergot before the os is dilated or ready to dilate, since it is unknown among intelligent physicians, hardly need to be referred to.

Supposing, however, after taking all possible precautions, laceration of the cervix occurs, as it sometimes must of necessity, what is the duty of the accoucheur in order to remedy this trouble and prevent future uterine disease. The first indication was to keep the wound clean and disinfected; the second was to bring the lips as nearly together as possible by means of stitches, plasters, or compressors. The utmost cleanliness should be enforced. The nurse should be instructed to give three or four injections daily. Stitching was hardly to be thought of; plasters and compressors could not be employed. Dr. Forrest had recently experimented with elastic bands which were slipped over the cervix in order to keep the torn cervices approximated. This procedure was still in the experimental stage, and Dr. Forrest was not yet prepared to give the results of the treatment.

Subinvolution is a term that has been of late years in vogue among foreign pathologists. Dr. Forrest considered this condition not so much a cause of uterine disease as constituting in itself uterine disease. Normal involution of the uterus may be supposed to be completed in from twelve to twenty days, instead of from four to eight weeks, as usually supposed. Various conditions might interfere with the process of involution. Dr. Emmet says he does not remember treating a case of subinvolution without finding more or less laceration of the cervix. Laceration of the perineum is said to be a common cause. Septicæmia, especially when associated with laceration of the cervix, is a most potent cause of subinvolution. The obstetrician is more frequently responsible for septicæmia than almost any other complication that may occur during labor.

Loss of blood, general debility, nervous excitement, too early leaving the bed, may all be causes of subinvolution. Subinvolution may be avoided to a greater or less extent by tonics, small doses of ergot or the wine of American ash. The patient should be kept in a recumbent position, with an undisturbed mind, and, above all, the utmost cleanliness should be maintained.

The last and most important portion of this paper, the author stated he was unable to put in shape for reading for want of time.

DR. BECKWITH agreed with the author as to the advisability of examining all patients for laceration within six weeks after labor.

DR. CASTLE said that he was not entirely prepared to accept the author's conclusions in regard to the *rationale* of laceration of the cervix. There was at least one cause for delayed labor in the first stage which the author did not mention, namely, slightly narrowed pelvis. This he believed to be the real cause very frequently, when it was supposed to be due to rigidity of the cervix. Another statement which he would make was in regard to the œdematous condition of the distended cervix. He believed that the softening which takes place during the first stage of labor was due to œdema, and hence it was desirable that œdema should exist. The hydrostatic pressure exerted upon the cervix by the bag of water was another factor favoring an œdematous condition of the cervix. In cases of early rupture of the bag of water we meet with rigid non-œdematous cervix.

DR. C. C. LEE felt no little diffidence in expressing his dissent from some of the views contained in the paper, partly because of the great worth and value of many of the suggestions contained in it, and partly because of the author's absence. In many points he agreed perfectly with Dr. Forrest. He believed, as did Dr. Forrest, that in a majority of cases of laceration of the cervix, it would be found that delayed labor was the cause. He had also looked upon the œdematous condition of the cervix as one of the causes of laceration. When excessive laceration of the cervix occurred, it could be detected upon the introduction of a speculum by the bright red blood flowing from the torn surface, in contradistinction to the small quantity coming from the fundus. He referred to three cases in which he had resorted to reparative operation immediately after severe laceration of the cervix. In the first he used silk stitches, in the second wire, and in the third serre-fines. All three operations were most signal failures. From this experience, he had resolved never to attempt the operation immediately after delivery unless hemorrhage was so profuse as to endanger the patient's life.

DR. LUSK called attention to the fact that there were two kinds of rapid labor, one in which the os was undergoing an imperceptible relaxation for days or weeks, after which a few sharp pains would result in the speedy delivery of the child. In these cases lacerations were very infrequent. There was one other class of rapid labor, in which the pains began without this previous relaxation on the part of the cervix. Patients would from the very first bear down, and thus by a voluntary muscular effort force the head through the unprepared cervix, under which circumstances very bad lacerations were apt to occur. He called attention to the fact that in the use of the forceps traction should be made during the intervals of pain, and should cease immediately upon the beginning of pain.

TRANSACTIONS OF THE OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, November 2, 1882.

THE PRESIDENT, EDWARD L. DUER, M. D., IN THE CHAIR.

DR. ROBERT P. HARRIS exhibited *Twenty-three Casts of Female Bony Pelves*, illustrating the varieties of deformity affecting labor. They were obtained in Paris, by Dr. T. Hewson Bache, for the Museum of the College of Physicians.

PURPURA HEMORRHAGICA.

DR. HENRY BEATES related the history of a child healthy for the first four months of its life, at which age it was attacked by thrush; ten days later an ecchymosis of purpuric character appeared on one leg, and a few days later spots of the same character appeared over the body; on the fifth day the stools were tarry, showing intestinal hemorrhage; the bronchial secretion was also stained with blood; on the seventh day a hemorrhage started from an abraided spot on the perineum; various local styptics were applied to this spot without result, until a red-hot needle was used as a cautery; on the tenth day a hemorrhage occurred from the canthus of one eye, and on the fifteenth day the child died from exhaustion. At the autopsy the internal organs were found quite exsanguine.

DR. BEATES also reported a case of

BURSTING PELVIC CYST.

The patient had been for some time in poor health. Nine months ago she observed a tumor in the right iliac region. On one occasion, after slight exertion she felt something give way; this was followed by intense pain and collapse. She recovered and has had no return of the tumor.

HEMORRHAGIC DIATHESIS.

DR. WM. SAVERY related the history of a boy, five years of age who had fallen and received a slight wound of the scalp from a nail sticking out of a post. It was a mere scratch, and did not need a stitch to hold it together, but it bled profusely. All sorts of domestic remedies, including cobweb, had been tried without avail. The doctor finally succeeded in arresting the hemorrhage with lint wet with Monsel's solution and continued firm pressure. A few days later the same boy fell off of one step on to the floor. There was no external wound nor loss of blood, but the side of the face was enormously swelled from hemorrhage into the tissues. A course of iron and tonics has improved the boy's appearance, but he is still pale.

DR. HARRIS inquired if there was any history of hemophilia in the family? Had the boy large knee-joints? There is a hemorrhagic diathesis entirely distinct from true hemophilia. The latter is rare in cities, but is more frequent in the country. The descent is through the females of a family but the disease appears only in the males; the Jews in certain districts of Germany present many examples. There is a remarkable family near Elkton, Md.

DR. SAVERY replied that there were no evidences of hemophilia in the family. The mother was pallid, had red hair, but did not lose much blood in labor.

DR. HORACE WILLIAMS had seen a case of obstinate and prolonged hemorrhage after the extraction of a tooth; it was finally stopped by fitting a cork into the alveolar cavity. An infant aged nine days was attacked with purpuric spots over the body and bleeding at the navel. To the latter were applied successively styptic colloid, tannin, Monsel's solution, Monsel's salt in powder, and finally transverse pins and figure-of-eight ligatures; but the bleeding reappeared as soon as the latter came away, and the child finally died from loss of blood.

DR. R. H. CLEEMANN had under his care a young man who had previously suffered from profuse hemorrhage for two days, consequent on the extraction of a tooth; the hemorrhage was finally stopped by Dr. Hartshorn, who plugged the cavity with a styptic. Dr. H. advised the young man never again to run the risk of a hemorrhage of any kind, as it would probably prove fatal. Recently he had been suffering from a toothache which nothing but extraction could relieve. Dr. Cleemann put him on gallic acid internally and tannic acid locally for two weeks before the extraction, which was accomplished without any unusual loss of blood. In a case of nasal hemorrhage, the anterior and posterior nares were plugged, but then ecchymosis appeared around the eyes and the plugs were removed; transfusion of a few ounces of blood was employed and the hemorrhage ceased and did not return; the patient died three months later of phthisis.

DR. E. L. DUER considered gallic acid a very valuable remedy for hemorrhage. He would like particularly to bring before the society, the old but neglected remedy, erigeron or flea-bane: the tincture and the volatile oil are very efficient when used internally to stop hemorrhage. The oil may be given in doses of ten drops every ten minutes until the bleeding is checked, after which it may be continued at longer intervals until the tendency has passed away.

DR. GITHENS had been using oil of erigeron for a number of years with remarkable success as an internal hemostatic. It was far more reliable than any other with which he was acquainted.

IMPERFORATE RECTUM.

DR. GITHENS reported an autopsy which he had performed that afternoon upon a baby aged twelve days, that had died from occlusion of the bowel. The anus was perfect, but as no meconium was passed, an examination of the rectum was made; the latter was found to be a cul-de-sac about one and a half inches in depth; as a tumid swelling could be felt above, a nick was made at the upper extremity of this cul-de-sac, and gas and meconium escaped; two days later it was found necessary to enlarge this opening, but at no time did any solid fecal matter pass, nor did the color of the milk appear in the feces. Death occurred from collapse from escape of the contents of the bowel into the peritoneal cavity. At the autopsy the rupture could not be found; the transverse colon was filled with well-digested milk; the upper part of the descending colon doubled sharply on itself and was bound down tightly to the posterior wall of the abdomen, there being no mesocolon on the left side; the lumen of the colon at this point was also obstructed by a hypertrophied fold of mucous membrane, which formed a septum reaching half across the colon, and had prevented the passage of the solid portions of the feces below that point; the rectum was distended with semi-liquid dark fecal matter.

A very remarkable circumstance in connection with this case is the fact that a former child of the same parents died at the end of the third day, there having been no discharge from the bowels, and the mother's aunt, on her mother's side, had lost five children out of seven, from the same cause; one of the five had been operated upon, but the condition returned after the lapse of six months.

The report of the *microscopical examination* of specimens presented at the last meeting by Dr. Wm. Parish, was made by DR. H. BEATES.

The specimen removed from the cervix uteri of case No. 2, is carcinoma of the encephaloid type.

The small tumors taken from the uterine cavity of

case No. 1, for the relief of continual hemorrhage, prove, on section, to be hyperplastic glandulæ utriculares, mucous membrane, and parenchyma. The intimate relationship of the uterine mucous membrane with the muscular structure is clearly shown, and the features of clinical interest in this instance well demonstrated. The mucous follicles or glands located on the free border in considerable number indicate that the growths originate from the fundus. The follicles are the seat of active epithelial proliferation and papillomatous degeneration, which latter process, it may be remarked, is *not* characterized by the regular relationship of cells to vessels seen in typical or benign papilloma, but by large multi-nucleated, irregularly shaped cells arranged in groups without any apparent regularity or system. This condition is strongly suggestive of carcinoma. The lesó-fibres are found to be infiltrated in many places by proliferated epithelium cells, showing that the morbid process involves the parenchyma.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, October 26, 1882.

THE PRESIDENT, JAMES TYSON, M.D., IN THE CHAIR.

HYPERTROPHY OF THE PROSTATE GLAND, ACCOMPANIED BY PROFUSE AND FATAL HEMORRHAGE.

The case was presented by Dr. J. B. Roberts for Drs. J. M. Adler and William Hunt.

The clinical history furnished by Dr. Adler is as follows: The patient, aged 66 years, of medium size, weighing 150 pounds, of regular habits, had enjoyed good health until within one year past. On a number of occasions during the past year he has had slight hæmatinuria. He passed his urine with ease, and only complained of slight perineal pain. On 12th of September last he arose in the morning in his usual health, but soon after breakfast he was attacked with sudden, acute pain in the bladder which he was unable to empty. Dr. Adler saw him in a short time, when the patient complained of great hypogastric pain and was much prostrated, with a blanched, sallow, cold skin, and a rapid and feeble pulse. A well-defined pyriform swelling occupied the hypogastric region, extending upwards to the umbilicus. After stimulants and morphia had been given, about one pint of fluid blood was drawn off by the catheter, after which, this instrument becoming blocked, a double one was introduced by means of which injections of warm water were thrown into the bladder, and another pint of broken-down coagula was removed. A solution of alum, 20 grains to the pint, was then introduced into the bladder and allowed to remain. Despite the internal use of ol. terebinth. and ol. erigeron., with opium suppositories, the hemorrhage continued, necessitating recourse to the catheter, injections, etc., to free the bladder from coagula. Death ensued on the sixth day from exhaustion induced by the repeated hemorrhages. The diagnosis arrived at by Drs. Hunt and Adler was carcinoma of the neck of the bladder.

Sectio cadaveris: The autopsy was a partial one, made in the undertaking establishment. Upon incising the hypogastrium, the distended bladder was at once seen, containing nearly a pint of clotted blood. This was removed by the hand through an opening in the viscus, when Dr. Roberts felt near the vesical neck, protruding into its interior, a pear-shaped mass, about the size and shape of the adult uterus. This, as the members of the Society saw, was evidently a greatly enlarged middle lobe of the prostate gland covered by unaltered mucous membrane. The lateral lobes were also enlarged. The mucous lining of the viscus was smooth and congested, presenting at one point two small circular depressions with clearly cut edges. Owing to circumstances, no further examination of the body was made.

DR. ESKRIDGE inquired whether the blood removed from the bladder at the autopsy presented an urinous odor. He had treated recently an interesting case of recurring hæmaturia, supposed to be due to a varicose condition of the veins of the vesical neck. The patient was a man æt. 77 years, who five years ago, and at intervals since, had lost considerable blood. The former attacks had yielded readily to ergot, but shortly after the onset of the last one, Dr. Eskridge had found the bladder distended with a large clot which he had been unable to break down by either alkaline or acid solutions. The secretion of urine was suppressed during the last twenty-four hours of the patient's illness, the blood drawn from the bladder presenting no characteristic odor. The man died apparently from uræmia, two or more severe chills preceding death, although no convulsions occurred, and he remained conscious to the last. Unfortunately, no post-mortem examination was obtained.

DR. FORMAD thought that the growth resembled rather a sarcoma than a carcinoma. He had seen two instances of round-celled sarcoma of the prostate. All growths starting from the epithelia of the genito-urinary tract, as well as from the cavity of the uterus, the kidneys and supra-renal bodies; in short, growths of all the organs arising from the middle layer of the blastoderm microscopically resemble sarcoma, and usually prove to be such when microscopically examined.

DR. TYSON said that this specimen possessed a special interest for him, inasmuch as he had had his attention forcibly directed to the differential diagnosis of a simple hypertrophy of the prostate from malignant disease of that organ, by having lately under his care a gentleman where ergot at first proved of much benefit, but in whose case the catheter was soon demanded. This instrument was used with unusual skill and gentleness by the patient himself, notwithstanding which blood occasionally followed its use. Exceedingly severe pains next developed, radiating from the bladder to the testicles, groins, and inner aspects of the thighs. Emaciation soon set in, and he died at the end of 15 months. At the autopsy malignant disease of the prostate was found, involving by infiltration the lateral aspects of the bladder and the neighboring parts so as to compress the nerves, thus accounting for the radiating pains complained of. He would like to know from Dr. Roberts whether his case presented this symptom of radiating pains, and also the source of the hemorrhage, as the smooth surface of the growth and the healthy condition of the mucous membrane of the bladder are such as to excite surprise.

DR. ROBERTS, in reply to the various questions propounded, said that only having made the post-mortem examination, he knew nothing beyond the facts given in the notes read. As to the source of hemorrhage, he would call attention to the two small erosions of the mucous membrane of the bladder as the probable source.

Report of the Committee on Morbid Growths: The specimen presented by Dr. Roberts, upon microscopic examination, is found to consist of the histological elements composing the prostate gland. There is no evidence of any neoplasm, except a numerical hypertrophy of the structures of the organ. The specimen is an hypertrophic prostate gland.

CASEOUS DEGENERATION OF THE KIDNEYS

presented by DR. J. B. ROBERTS for Dr. Dunmire. Owing to Dr. Dunmire not having seen the woman until within a few hours of death the history is of necessity imperfect. She was a married woman 39 years old, whose husband

is said to have infected her with some form of venereal disease. The husband had been dead for about one year when the patient first came under treatment. There were no evidences of syphilis, so that the supposed venereal affection of the past had been presumably gonorrhœa. When seen September 14, 1882, was exceedingly ill, gave a history of general ill health for the past few years, but dated the present trouble some weeks back when she had bathed in the surf while menstruating. This was followed by a chill, since when she had steadily grown worse. When Dr. Dunmire saw her, she complained of sore throat, difficult deglutition, anorexia, sick stomach, pain in the back, with sharp pain running towards the groin, especially on the right side, tenderness over the abdomen, and frequent scanty micturition. The pulse was 140, the temperature 103°, and there was profuse leucorrhœa. An unfavorable prognosis was given, which was soon verified by her becoming unconscious and dying six hours later.

Autopsy: The abdomen alone was allowed to be examined. All organs healthy except kidneys and bladder. The latter contained a little urine and mucus, its walls were much thickened, and its lining membrane was congested. The left kidney had little true kidney structure left, but was converted into a group of seven or eight cysts containing a white cheesy material of a moderately firm consistence. The ureter was much dilated and thickened for about three inches from the pelvis of the kidney. The right kidney was normal in outline, but when incised revealed one large cyst with creamy contents, and also another small cavity containing a few minute calculi. Several of these could be felt through the walls of the normal ureter, thus accounting for the ante-mortem renal colic. The perinephritic structures were unchanged, as well as the capsules of the kidneys, although these latter were perhaps more adherent than normal.

TUMOR OF THE MEDIASTINUM

exhibited by Dr. W. S. LITTLE for Dr. G. C. Smith, of Rondout, New York.

The history of the patient from whom these specimens were removed is in brief as follows: A young man æt. twenty-four years, had been but a few days under Dr. Smith's care, having come from Boston, where his physician had pronounced him phthisical, and had recommended a sea voyage. During the past few months small nodular masses had developed in the muscular tissue of the right chest-walls, near the median line in front, and also posteriorly. The axillary and supra-clavicular glands were involved. Shortly after Dr. Smith first saw him he developed marked dyspnœa, and died suddenly, without any evidences of marked lung disease, except, perhaps, some symptoms of pleuritis. There was apparently mitral disease. Anasarca, especially of the lower extremities, gradually developed.

Sectio cadaveris: The skin was hard and friable; nodular masses were found disseminated through the muscular tissue of the chest-walls, which had undergone some species of degeneration; the costal cartilages presented evidences of a degeneration similar to that seen in the muscle. On removing the sternum, the subjacent tissues were markedly pigmented, and the anterior mediastinum completely obliterated by a mass of the size and shape of the half of a large lemon, which pressed against the heart. The large bronchi were involved in the growth, otherwise the lungs seemed healthy, and evidences of slight pleurisy were found. The pneumogastric nerves were both involved, chiefly the left, and on further dissection the disease was found to occupy all of the lower part of the posterior mediastinum, involving the contiguous osseous tissues. The nerve involvement explains the sudden death. The diaphragm was also involved in the lower portion of the growth. The four portions of the growths shown to the Society are, 1st. One of the subcutaneous nodules; 2d. A small portion of the left lung, near its root; 3d. A portion of the anterior mediastinal growth, with part of trachea, bronchi, and aorta; 4th. One-quarter of the tumor, which involving the diaphragm, projected from the left thoracic wall into the chest cavity.

Dr. Formad inquired whether there were any other evidences of cancer in the remainder of the body.

Dr. Little replied that none were detected.

Dr. FORMAD said that he was unaware of any specimen of primary carcinoma of the mediastinum on record, and moved the reference of the specimen to the Committee on Morbid Growths, as it was probably a sarcoma.

Report of the Committee on Morbid Growths: "The mediastinal growths are found on microscopical examination to consist of a mass of hypertrophic lymphatic glands, much pigmented. There are also seen adipose and fibrous tissues in a state of active proliferation."

CIRRHOSIS OF LIVER IN THE STAGE OF ENLARGEMENT

exhibited by Dr. E. T. BRUEN. F. W., aged 20 years, colored, has worked on farm since boyhood, and has been much exposed to weather. His habits were temperate, he was free from either syphilitic or malarial taints. Father is still alive, the mother died of phthisis. He was never robust, but had had only one severe illness, viz., typhoid-fever, from which he convalesced perfectly, but he readily "took cold." He was first seen by Dr. E. T. Bruen, at the University Hospital, in January, 1882, when he gave the following history. Abdomen began to swell two years ago with neither pain nor tenderness. Was obliged to rise at night to urinate. As abdominal swelling increased and the previously regular bowels became constipated; occasionally sharp, shooting pains were felt across the chest when lifting weights, or working hard, and also slight dull pains over liver, lasting for a few moments only. When seen, abdomen measured 50 inches. On 19th of January, he was tapped, 19 quarts of fluid being removed, rendering plain a much enlarged liver, covered with smooth nodular elevations, with the apex beat of the heart displaced upwards into fourth interspace. March 18th, five gallons more fluid were removed, after which pleural and bronchial complications arose, which soon subsided. May 6th, paracentesis by capillary needle was resorted to, which was followed by much localized tenderness around the site of the puncture, and peritonitis set in, which terminated life the same evening. During life the diagnosis was most difficult and interesting, the enormous size of the liver, the palpable bossellation of its surface, giving a sensation like that of crepitating tissue, as though fluid lymph had been thrown out, and finally his abstemious habits, with absence of either syphilitic or malarial taint, suggested malignant disease. His age, the excessive rarity of primary carcinoma, or sarcoma of the liver, with his family history all negatived this view. He had had some dyspepsia; enlargement of the liver connected with catarrh of bile-ducts, would have presented symptoms of jaundice and intermitting temperature, terminating by death from cholesteremia. The case then was one of simple cirrhosis.

Sectio cadaveris: The abdomen contained six gallons of purulent fluid. Both the parietal and visceral peritoneum were covered with a thick coating of inflammatory lymph tinged with blood, from multiple capillary hemorrhages. The abdominal veins were all replete with blood. The liver weighed nearly 5½ pounds, was of a nutmeg appearance, on section was indurated, and presented a bossellated nodular appear-

ance. The gall-bladder was thickened and contracted about two-thirds in bulk. Bile-ducts were normal, the spleen was covered by a pseudo-cartilaginous capsule, but was otherwise normal, as were also the stomach, pancreas, intestines, kidneys, and supra-renal bodies. The abdominal lymphatic glands were slightly enlarged.

DR. SEILER remarked that, having seen the case during life, it was almost impossible to divest one's self of the idea of malignant disease. He thought that the projections were unaltered portions of the liver, which had been compressed and squeezed out by the contracting interstitial tissue.

Dr. Bruen remarked upon the obscurity of the etiology.

DR. TYSON asked Dr. Formad, who had examined the specimen microscopically, whether he considered it to be in the first or second stage of the affection.

DR. FORMAD replied that he considered it to be in the commencing second stage, and detailed the microscopical appearances.

DR. TYSON, after briefly adverting to the causation of cirrhosis, said that his reason for asking Dr. Formad whether he considered that the organ was in the first or second stage of cirrhosis was, that some few years since an important insurance case had been argued in our courts where the defence was set up that the man had not a cirrhosed liver because it was enlarged. For his part he had no doubt that a liver could be in the second stage of cirrhosis and yet be enlarged; there might be enlargement from fatty infiltration concurrent with interstitial inflammation.

CORRESPONDENCE.

THE NON-IDENTITY OF CROUP AND DIPHTHERIA.

To the Editor of THE MEDICAL NEWS.

SIR: In your issue of October 21, there appeared a lecture delivered by Dr. Morell Mackenzie, of London, at Bellevue Hospital Medical College, on "Diphtheria." In that lecture the learned Doctor pronounced croup and diphtheria one and the same disease. This is an utterance *ex cathedra*, and deserves more than passing notice.

I do not think that the *ipse dixit* of this distinguished authority is sufficient to establish his doctrine of identity in regard to those hitherto considered separate diseases. But he goes farther, and states: "I believe though, after all, it is a mere theoretical question." I think it is very much more, not as far as the medical treatment is concerned, but it is of very great importance in regard to the question of contagiousness.

Diphtheria has been regarded as a most contagious disease. Croup has not been so regarded. In the one case it has been the rule to isolate the patient, quarantine the family, and exclude the other children, if there any, from the public schools for a certain specified time. In the other case there has been no isolating, no quarantining, or limitation of personal freedom. If these diseases are identical, why this exhibition of inconsistency, why this wanton trifling with human life in the neglect of proper precautionary measures? If the members of the medical profession are to be regarded as the guardians of the public health, this question of the identity or non-identity of these diseases is of much more importance than a merely "theoretical question."

During an active practice of twenty years I have had quite a number of cases of membranous croup under my care. During ten of these years there has not been one case of diphtheria in the district, yet during these years an occasional case of true croup would appear, and in none of them was any attempt ever made to prevent the spread of the disease. Yet no second case ever occurred in the same family, nor were any other members of the household afflicted with sore throat of any kind near the time when the cases of croup arose.

In some of the cases that proved fatal, there were quite a number of other little children in the same family. These had constant access to the bed of the suffering one, and after death for two or three days, while the body remained in the house, these little ones would hover around where it was lying, and many fond kisses were showered on the loved form, and yet I have never had a second case in the same family. On the other hand, I have had cases of diphtheria when every effort was put forth to prevent the spread of the disease, and while I might now and again succeed, yet in the large majority of cases the disease would spread in the face of all that I could do.

Now with facts such as these before me, and my experience does not differ from that of many others, is it any wonder that without something more than mere assertion I should still very respectfully maintain that croup and diphtheria are *two* and distinct diseases, the one a highly contagious disease, the other not in the slightest degree contagious.

In order to save the profession from well-merited reproach on account of so much diversity of opinion on this subject cannot a Medical Commission be appointed to deal with this matter and to arrive at some definite finding?

I remain, yours respectfully,

A. D. MACGILLVARY, M.D.

SYDNEY, C. B., NOV. 1, 1882.

PULVERIZED BORACIC ACID.

To the Editor of THE MEDICAL NEWS.

SIR: Boracic acid has of late come into such repute as a topical dressing in the treatment of otorrhœa and kindred catarrhal affections, and as the best results follow its use in a pulverulent state, it may not be amiss to state a method by which it may be reduced to a powder.

A few moments' trituration of a small quantity of the acid will prove to the most experienced the futility of the present method.

When our attention was first directed to the subject, we adopted the plan of heating the acid in an evaporating dish, stirring continually, until it assumed a granular state, or in other words became partially decomposed into boric oxide by loss of water. If at this time a small quantity of water was added, and the mass allowed to stand for an hour or more, the partially decomposed acid resumed its original state, but when dry in an impalpable powder. The method, however, was expensive, as a notable per cent. of the acid was lost by volatilization.

Further experiment showed that trituration while moistened with water was all that was needed to reduce it to a pulverized condition, although not as fine a preparation as that by the former method. The operation is facilitated by removing from time to time the finer portion by means of a bolting cloth—the face cloth on Mead's adhesive plaster answers nicely. The use of aromatized water adds to the elegance of the preparation.

I am, sir, yours, etc.,

GRANVILLE FAUGHT.

CHARLESTON.

(From our Special Correspondent.)

DENGUE OR BREAKBONE FEVER is again present in this city. It began to be recognized by the physicians here about six or eight weeks since. It has prevailed pretty generally, and we will look with interest to see what influence ice has upon it. Dr. Thomas, of Savannah, in a contribution on "The Dengue of 1881," to the *Transactions of the Public Health Association* (vol. vi.), contends that frost and ice did not destroy the disease in Savannah. Our observations here are to the effect that no greater proportion of cases occur after the advent of frost than we find after the similar prevalence of an epidemic of yellow fever.

The present epidemic of dengue is comparatively mild, though pretty generally diffused. There is the characteristic and marked features of pain and fever. The latter often continues for from two to six days, accompanied often by eruptions and headache. It is often ushered in by an ague or by chilly sensations, and very seldom, as far as our experience extends, by the presence of swelling of the joints, by boils, or, in the case of females, by miscarriages or hemorrhages.

We think that a malarial element seems clearly marked in most cases—there being regular intermissions—the fever appearing and disappearing from time to time. There are no catarrhal symptoms or other signs of influenza. The prostration is not nearly so great as in previous epidemics. This city has been otherwise remarkably healthy, scarlet fever and diphtheria having apparently disappeared from the bills of mortality. As respects treatment, we find that the disease readily yields to alkaline fever-mixtures, cold sponging of the head, hands, and arms, hot mustard pediluvia and quinia given during the intermissions. Opium does not seem to have been required. The pain is relieved by hot mustard baths. The following fever-mixture has been found efficacious here:

℞—Acetate of potash,	ʒij.
Spirits of nitrous ether,	ʒij.
Liquor ammoniæ acetatis,	ʒj.
Muriate of ammonium,	ʒj.
Water,	ʒiv.—M

S.—A teaspoonful every two or three hours, when there is fever adding one or two drops of tincture of root of aconite to each dose.

The period of incubation in dengue may be as short as three or four hours—much less than was reported in a paper in the recent issue of the volume of *Transactions of the South Carolina Medical Association*. Both Dr. Wragg and Dr. Wappold mention a few hours as the incubation period in their sketches of earlier epidemics of dengue here, published in vol. vi., 1881, of the *Charleston Medical Journal and Review*. This also agrees with our own experience of former epidemics.

MONTREAL.

(From our Special Correspondent.)

MONTREAL MEDICO-CHIRURGICAL SOCIETY.—At the annual meeting the following gentlemen were elected officers for the ensuing year:

President.—Dr. Kennedy.

Vice-Presidents.—Dr. G. Roddick; Dr. Rodgers.

Secretary.—Dr. Henderson.

Treasurer.—Dr. Molson.

Librarian.—Dr. Gurd.

Council.—Drs. F. W. Campbell, Osler, and George Ross.

THE LATE DR. A. H. DAVID.—The death, in this city, on November 5, of Dr. A. H. David, aged seventy years, removes almost the last survivor of the older generation of practitioners in Montreal. Born in this city, in 1812, he was educated at McGill College, and afterwards at the University of Edinburgh, where he graduated in 1835. Returning to Canada he practised for some years at Three Rivers, but since 1844 has been a resident of Montreal, and an active and zealous member of the profession. In 1852 he edited, with the late Dr. R. L. Macdonnell, the *Canada Medical Journal*, which was discontinued after the first year. About the same time he participated in the establishment of the St. Lawrence School of Medicine, which only held two or three sessions. In 1870 he, with others, established the Medical Faculty of Bishop's College, in which he was the Professor of the Practice of Medicine, and was the Dean almost from the inception of the school. He was the General Secretary of the Canada Medical Association from its foundation until last year, when serious illness compelled him to retire. Dr. David was President of the Natural History College of Montreal, and Governor of the College of Physicians and Surgeons of Lower Canada, and was Corresponding Member of the Literary and Historical Society of Quebec, Extraordinary Member of the Royal Medical Society of Edinburgh, Corresponding Member of the Gynecological Society of Boston, Member of the British Association for the Advancement of Science, and Member of the American association for the same. For more than two years he suffered with cancer of the rectum, and bore his painful illness with remarkable fortitude and resignation.

PROGRESS OF THE YELLOW FEVER.—The following reports of cases at *Brownsville, Texas*, for the period ending *November 6, 1882*, have been received by the United States Marine-Hospital Service:

	Cases.	Deaths.
Week ending Nov. 4, 1882,	23	0
November 5 and 6, 1882,	4	1
Total number since first appearance,	2004	115

One case at Point Isabel, November 4.
Seven deaths at Camargo, Mexico, November 3.
Eleven deaths at Mier, Mexico, November 2 and 3.

Pensacola.—The sudden decrease in the number of cases reported from Pensacola during the course of this week evidently indicates an interference with the spread of the infection by meteorological or other incongenial influences rather than the exhaustion of the susceptible material among the inhabitants. The daily reports to the National Board of Health have been as follows:

Dates.	Cases.	Deaths.
October 31,	7	4
November 1,	11	0
" 2,	7	1
" 3,	9	2
" 4,	10	2
" 5,	15	0
" 6,	6	1
	65	10
To October 30,	2178	175
Total reported to date,	2243	185

The investigation into the origin of the epidemic undertaken by the National Board of Health appears to meet with obstacles at every point. First, Major Walthall, who was expected to prosecute this inquiry, found it impossible to spare the necessary time, from more urgent duties in connection with the sick of the

city, and now Dr. Martin, U. S. N., who, after much and troublesome preliminary investigation, had just begun to feel that he was on the right track, is prostrated by the fever. He was taken sick on the 2d inst., but is progressing favorably under the care of Dr. Hargis, president of the Board of Health of the city. It is understood that Dr. Martin proposed to devote some attention to the history of certain "second attacks" which had been reported in Pensacola. Inasmuch as his own case comes under this category as well, we believe, as that of his attending physician, who has but recently recovered, he will be able to speak *ex cathedra* on this subject.

The navy yard continues free from fever by virtue of its *cordon sanitaire*, notwithstanding that it has been for so long within sight of infected localities. Dr. Owen must feel gratified not only that his seventeen hundred people have been saved from infection and its dangers but that a demonstration has been given as well of the non-indigenous nature of the disease as of the necessity for a less subtle medium of communication than is afforded by the air. But although the yard and its dependencies have been preserved from yellow fever, a febrile epidemic of another color has been rife during the past few weeks. How the infection was introduced is unknown, but since the cordon was established and all communication with the outside world cut off scarlet fever of the anginose variety has appeared, and thirty-eight cases have been reported. Many unreported cases are presumed to have occurred.

THE RICHMOND COUNTY (N. Y.) MEDICAL SOCIETY AND THE NEW YORK CODE.—The following resolutions have been adopted by the Richmond County (N. Y.) Medical Society:

Whereas, The By-Laws of the American Medical Association exclude from representation any State or local society which disregards its Code of Ethics; and

Whereas, The Richmond County Medical Society has bound its members to observe the said Code; therefore

Resolved, That the Richmond County Medical Society repudiates the action of the Medical Society of the State of New York, in adopting the second section of the recently promulgated amendment to the Code of Ethics, and that our delegate at the next session of the State Medical Society be instructed to urge the rescindment of such action, which this society regards as subversive of the dignity and true interests of scientific medicine; and in the event of a reconsideration being refused, to withdraw from the State Society.

Resolved, That a copy of this resolution authenticated by the signatures of the President and Secretary be forwarded to the Secretary of the American Medical Association, to the Secretary of the State Medical Society, and to such medical journals as the President may designate.

THE NEW YORK COUNTY MEDICAL SOCIETY AND THE NEW YORK CODE.—The New York County Medical Society has elected a delegation to the New York State Medical Society which is understood to be pledged to vote to maintain the new Code.

THE RIGHTS AND DUTIES OF DELEGATES.—The *Detroit Lancet* (November, 1882) is "astonished that so wise a man as Dr. Jacobi, and such an able journal as the *Medical Record*, should recommend that delegates should pay no heed to the wishes of the county societies which shall send them to the next meeting of the New York Medical Society. The *Record* thinks that no delegate will forego his personal rights at the dictation of the society he is chosen to represent. It claims that each delegate has such a right as will permit him to violate the trust imposed in him by the society that he has engaged to represent. It is vain to say that the several societies do not fully understand the question of ethics as involved in the action taken last winter. When thus understanding it and when they select a delegate who accepts the position, they can expect nothing but that their wishes will be carried out by their delegate's voice and votes in the convention. The advice of the eminent gentlemen to the New York county delegates seems to us in the highest degree dishonorable. Evidently they do not think that the county medical societies of New York are giving their delegates proper instructions, since almost all thus far heard from have very positively signified their repudiation of the ethical code inaugurated at the last meeting. If the matter related to politics, the natural inference would be that while the leaders of the New York State Society felt able to deal with individual delegates after they had manipulated them at Albany, they were impotent to manipulate the several societies that really constitute the profession of the State. But of course, among medical men, in a matter such as the one before the profession of the Empire State, bribery or bulldozing of the delegates is impossible. We still believe that no honorable man will violate the instructions of the society sending him. His course is plain. If he does not think the wishes of his society are such as he can honestly endorse, he will at once resign his appointment, in order that the society may appoint such a one as will execute their will. In this manner all have perfect freedom to act, and speak, and think, and vote, as seem to them wise. The question in all possible relations has been discussed. What now remains is the voting. Let this be done fairly by all the county societies and we shall know the status of the medical profession of New York."

NATIONAL BOARD OF HEALTH.—The President has appointed George E. Waring, Esq., of Newport, R. I., a member of the National Board of Health, in place of Dr. Charles F. Folsom, of Mass., resigned.

MEDICAL POLYCLINIC OF THE NORTHEASTERN DISPENSARY, NEW YORK.—Arrangements have been made by which the Northeastern Dispensary of New York has been thrown open for the benefit of medical students and physicians; clinical instructions will be given to classes in gynecology, eye, ear, and throat diseases, skin diseases, nervous diseases, and diseases of the heart and lungs.

TRAINED NURSES.—The first annual commencement of the Brooklyn Training School for Nurses was held October 2d, in the City Hospital.

Mayor Low presided, in behalf of the president of the Board of Managers, Mrs. Seth Low, and after making a brief speech, in which he alluded to the success of the school, presented the diplomas to four graduates.

Dr. Joseph C. Hutchinson, who represented the City Hospital, delivered the address to the graduating class. He was followed by Dr. Benjamin F. Westbrook, who said that the ambulance surgeon reported that nearly all the victims of accidents or injuries coming under his observation had expressed their desire to be taken to the hospital where there were lady nurses. This the speaker considered a high tribute to the assiduity, watchfulness, and fidelity of the ladies who had graduated, and the best testimonial of the value and importance of a school which should furnish a proper system of education in training noble women in the duties of ministering to the invalid and afflicted.

At the close of the exercises in the hospital proper,

an adjournment was taken to the Nurses' Home, formerly the Orthopedic Dispensary, which was opened to the public for the first time. The building has been thoroughly reconstructed in the interior, and comfortable rooms have been fitted up for the thirty-one young ladies who now constitute the class of students.

DR. LUSK'S MIDWIFERY.—The *Medical Times and Gazette* for October 21, 1882, carefully reviewing Lusk's *Midwifery*, concludes, as follows:

"We thank Dr. Lusk for his most valuable work, which is, in our opinion, as we have said before, the best representative of the state of obstetric science and art at the present day that exists in the English language."

GRANT TO M. PASTEUR.—The French minister of agriculture has placed 50,000 francs at the disposal of M. Pasteur to enable him to continue his investigations on the contagious diseases of animals.

THE WARREN TRIENNIAL PRIZE.—The Warren Prize Committee offer a premium of $400 for the best dissertation worthy of a prize, upon the following subject:

"CHRONIC BRIGHT'S DISEASE (parenchymatous and interstitial nephritis). The nature and mutual relations of the derangements in the circulatory and secretory organs."

Dissertations should be forwarded to the resident physician, Massachusetts General Hospital, Boston, on or before February 1, 1883.

WESTERN MEDICAL CLASSES.—The Rush Medical College of Chicago, is said to have opened this term with a class of 470; the Chicago Medical College with 150, and the new College of Physicians and Surgeons of Chicago with over 100.

MEMORIAL TO THE LATE PROF. BALFOUR.—A meeting has been called in Cambridge to take steps as to the establishment of some memorial to the late Prof. F. M. Balfour. The vice-chancellor of the university announces that the family of Prof. Balfour has presented his scientific library to the university for the use of the Morphological Laboratory.

BALTIMORE EYE, EAR AND THROAT CHARITY HOSPITAL.—This institution is now open for the reception of patients. The attending medical staff is composed of specialists in the different branches indicated in the title, and the design of the institution is to furnish skilful medical and surgical treatment, and, where necessary, hospital accommodation for the indigent poor suffering from eye, ear, and throat diseases.

Connected with, and forming an important feature of, the hospital, is an *out-door department, or dispensary*, which is under the charge of the hospital medical staff. Clinical instruction and demonstration of cases will be given daily by the members of the medical staff.

RESIGNATION OF DR. O. W. HOLMES.—Though it has been for some time asserted that Dr. Oliver Wendell Holmes contemplated resigning the Chair of Anatomy in the Harvard Medical School, no definite announcement of the fact was made to the public until last week. At the request of the officers of the board of government, the resignation will be permitted to remain in abeyance until satisfactory arrangements can be made for permanently filling the vacancy, and for the present the Doctor will continue with his lectures to the first class of the school, which is the only one that comes under his department of instruction. His retirement is not enforced by ill-health or the inaptitude sometimes incident to increasing years, but is induced by his desire to give attention hereafter more particularly to literary pursuits. This decision on his part, while reluctantly consented to by the college authorities, will doubtless be viewed with complacency, to say the least, by the general public, who will argue that, while the technics of anatomy may be taught by another, there can be but one Dr. Holmes in literature. That his professional career has been one of great ability and usefulness, its continuance through a period of thirty-eight years proves. When Dr. Holmes was appointed to the office in 1847, it was known as the Parkman Professorship of Anatomy and Physiology. This title was retained until a date early in the administration of President Eliot, when the system of instruction here, as in some other departments, was expanded, and two professorships, one of anatomy and one of physiology, were established. For the former, Dr. Holmes was retained. Dr. Holmes's instructions have generally been given in the form of extemporaneous lectures, illustrated by anatomical preparations, models, pictures, and diagrams. In exceptional cases written lectures have been prepared. His professional literary labors have not been limited to these discourses, however, but have been productive of numerous contributions to the medical journals, occasional addresses before assemblies of medical men and a few published volumes. A nearly or quite complete list of these is, "Boylston Prize Dissertations," "Currents and Counter-currents," "Border-lines of Knowledge in Medical Science," and "Mechanism in Thought and Morals." The list of non-professional volumes which have been prepared, or which, at least, have served so well, as mental tonics, stimulants, and alteratives for the many who have eagerly purchased them, can be recited by anybody: The "Autocrat," the "Professor" and the "Poet at the Breakfast Table," "Elsie Venner," "The Guardian Angel," "Essays from the Atlantic Monthly," and one or two volumes of poems. As a labor of love, a memoir of John Lothrop Motley has been prepared and published in a handsomely bound and printed volume. In laying aside the gown of the professor, Dr. Holmes gains a well-earned exemption from hard work, and all will join in the wish that the pleasures of his literary "vacation," now about to begin, may be many and long-continued.

THE COMPLAINT AGAINST THE NEW YORK CREAM OF TARTAR WORKS DISMISSED.—Health Commissioner Raymond, of Brooklyn, has dismissed the complaint against the New York Cream of Tartar Works on Kent Avenue. In his decision he says: Whether the odors complained of constitute a nuisance in the eye of the law is a question which has not been and cannot be submitted to any decision of mine. The question is solely whether the health of so large a number of persons has been affected as to warrant a declaration that the public health is endangered, for to this the law confines the Board of Health, acting under the section already quoted. That this claim is not substantiated by the evidence there is, I think, no doubt, and that such danger is not likely to follow in the future, appears from the testimony, some of which I quote. Professor Henry Morton testified that the material used has no unhealthful properties, and that there is nothing in the process which is unhealthy; that no poisonous acids or unhealthy vapors get into the air; that there are no vapors which escape in the process which do not first escape into the building where the employés are at work, and thence into the air. Professor S. G. Armor testified that he examined these employés, and pronounced them healthy-looking men. Nor does it appear in the testimony that there has been any sickness

among the factory hands attributable to the vapors complained of. Dr. Joseph C. Hutchison testified that the odors and vapors which escape from the factory are neither poisonous nor unhealthful, and that some of them would have quite the opposite effect upon the atmosphere, and tend to purify rather than otherwise. The testimony of Dr. S. Fleet Speir is to the same effect in regard to the absence of detriment or danger to health from these vapors and odors. After a full and careful consideration of all the testimony in the case, I am compelled to decide that the business complained of is not detrimental or dangerous to the public health, within the meaning of the statute.

The Office of Assistant Surgeon-General.—The Attorney-General has just submitted an opinion to the Secretary of War to the effect that a vacancy in the office of Assistant Surgeon-General can be filled by the appointment of any surgeon with the rank of colonel, or it may be filled by appointing thereto the senior officer in the medical corps having the rank of lieutenant-colonel, which is the next grade below. The latter officer is, by the rules of promotion in the military service, entitled to the vacancy existing in the grade to which the office of Assistant Surgeon-General belongs.

Bequests to Medical Charities.—The late Jerome G. Kidder, Esq., of Boston, has bequeathed $50,000 to the Boston Lying-in Hospital, and $25,000 to the Massachusetts General Hospital.

Mr. Francis Seymour Haden, of London, and member of the Royal College of Surgeons of England, has just arrived in this country. In addition to his surgical attainments, Mr. Haden is an etcher of considerable reputation, and comes to this country to lecture in the principal cities on art subjects.

Holy Water.—The *Chemical Review* states that recent analysis of the water from the Holy Well at Mecca, which is so eagerly drunk by pilgrims, shows this water to be sewage, about ten times stronger than average London sewage.—*Lancet*, October 21, 1882.

Isolation of Cases of Contagious Disease in School Children.—The French Minister of Public Instruction has addressed a circular to the editors of the French Medical Journals asking their assistance in urging the universal adoption of the rules drawn up by the committee of the Académie de Médecine as to the time children should be kept from school after exposure to contagious disease; these rules have been already published in The News for August 12th.

The New Obstetrical Institute of Vienna, already mentioned in our columns, will open at the end of this month instead of on Sept. 1st, as previously announced.

Samaritan Schools.—Professor Esmarch, the well-known surgeon of Kiel, recognizing the advantages of immediate attendance in cases of accidents, has instituted a number of schools in that city which are called Samaritan schools. They are composed of youth of both sexes, who are so instructed that in case of accidents they can render every assistance necessary until the arrival of the physician. Professor Esmarch has written a small work upon the subject, in which he explains the various means to be employed under such circumstances. The scholars are instructed upon the formation of the bones and action of medicines in a few hours. In consequence of the success which has attended these schools, the Professor has visited Berlin for the purpose of introducing the system there. Eight schools, of 40 students each, have been established in that city. Many of the most prominent physicians lecture and give demonstrations upon the structure of the human body. An important feature of this innovation is the enrollment of a portion of the police force among the scholars. It may be supposed that a policeman thus trained will be able to distinguished between cases of illness and intoxication, and not take victims of the former to the lock-up, as sometimes has happened. —*Boston Journal of Chemistry*, November, 1882.

The Evil Effects of Badly Made Shoes.—At a recent meeting of the Hygienic Congress at Geneva, Colonel Ziegler, who is chief surgeon of the Federal Army, read a paper on the evil effects of badly made shoes, with special reference to hygiene and the marching powers of soldiers. Colonel Ziegler mentioned that the Swiss examining surgeons are compelled to reject every year 800 recruits—the strength of a battalion—for malformation of the feet, resulting from badly fitting shoes. The foot is in reality a bow, so elastic that at every step it contracts and expands, lengthens and shortens, and a line drawn through the centre of the great toe intersects the heel. But shoemakers, who are generally utterly ignorant of the anatomy of the foot, do not give room enough for the lateral extension of the great toe. They crib, cabin, and confine it until it is forced against the other toes. Hence arise frequent inflammations of the great toe, corns, ulcerations, and sometimes veritable articular inflammation. Another evil, which Colonel Ziegler ascribes in great measure to bad shoeing, is flat-footedness, whereby the arch is converted into a straight line, and prolonged walking and marching rendered impossible. Another cause of this defect is the habit of carrying heavy weights at an early age; but in most instances, Colonel Ziegler contends, perfect shoes would restore the foot to its normal condition. The first obstacle to a reform in the shape of shoes lies in the fact that it would involve a great expense in the shape of new lasts, an expense that shoemakers are naturally loth to incur. Fashion has also its lasts, and shoemakers consider themselves bound to conform to the prevailing mode. A test of a perfect pair of shoes is that, when placed together, they should touch only at the toes and the heels; the soles should follow the sinuosities of the feet, and to give room for their expansion should exceed them in length by fifteen to twenty millimetres.

The Treatment of Hysteria by Metallo-therapy.—One of our indefatigable German *confréres* contributes in the *Archiv für heitere gynäkologie* the following instance of such successful treatment of this rebellious disease that we deem it worthy of notice. Marie O., a chamber-maid in the house of a Privy Councillor in Berlin, was compelled, among various other laborious duties, to light to the door the numerous guests who visited the house nearly every evening. The reporter had occasionally opportunity (she was charming, and nineteen years old) to notice how she comported herself to the visitors who attempted to call a smile to her lips by liberal "trinkgelder." This however, was no easy task: on account, probably, of some anomaly of menstruation, she was hysterical, apparently; always solemn, almost melancholy in her bearing; sometimes he even thought he saw tears in her eyes. This case of hysteria, thus clearly made out, seemed to him in every way suitable for the study of the influence of metals on the psychical state, and the reporter determined at the next evening reception to which he was invited to institute some experiment on this point. Accordingly he posted himself behind her

as the guests passed out in leaving the house: when nickel, copper, or silver in pieces of small circumference came in contact with her beautiful hand, the melancholic condition remained unaltered, became even indeed painfully exaggerated. A larger piece of silver, apparently about as large in size as a five-mark piece, seemed reflexly to call forth some transitory improvement. Suddenly, however, as a handsome young baron passed before her and with a meaning look pressed something into her outstretched hand, he believed that a complete cure had been accomplished; he looked closer—it was a gold ten-mark piece.

The above case is reported as showing the comparative value of gold and other metals in the treatment of hysteria; it would seem that, to be equally efficacious, silver must be applied in larger quantities than gold.

TOY-PISTOLS.—The report of the State Board of Health of Wisconsin for the current year gives the following information concerning this dangerous plaything: About the 4th of July last many accounts appeared in the columns of the public press of accidents occurring from the use of toy-pistols. These articles are of two or three kinds, some using a cartridge of thin tissue paper enclosing a minute quantity of fulminating powder; others making use of a composition of phosphorus and chlorate of potash similar to that sometimes employed for tipping matches; and others still have cartridges of copper, charged with nitro-glycerine, giant powder, or dynamite, tamped with clay. The first are the least objectionable; but, as a part of the cartridge consists of very fine gravel, which may be driven into the eyes by the explosion of the fulminate, they cannot be called safe playthings. The second kind, those in which the charge consists of a pellet of phosphorus and chlorate of potash are objectionable from the fact that the phosphorus is liable to cause burns which are difficult to heal, being poisoned by the acid produced during the combustion, and which leave unsightly scars. It is true that the liability to such accidents may be decreased by a very careful and exact proportioning of the ingredients of which the cartridges are composed, but a knowledge of chemistry sufficient for this is hardly to be looked for among the workmen employed by the manufacturers. The third, however, is doubtless the variety to which the accidents already referred to are due; these accidents are always very severe, and in several instances have ended fatally. Their cause is briefly this: into all explosions the element of time enters to a greater extent than is usually suspected, and on the rapidity with which combustion occurs depends very often the amount of damage done, or rather whether any mischief at all shall result. Gunpowder, which seems to explode instantaneously, is really among the slower of the explosives, and hence it may be used with a greater measure of safety than almost any other. Gun-cotton is variable in its action, and may be rendered slow or quick at pleasure; the fulminates are very rapid, while nitro-glycerine is almost uncontrolable—a property which at once gives rise to some of its most valuable applications and renders it especially dangerous in incautious or inexperienced hands.

A drop or two of nitro-glycerine placed in a thin copper shell in company with a minute portion of fulminate, and covered with clay, constitutes the cartridge furnished with the toy-pistols to which the serious accidents have been owing; this cartridge is placed in a roughly constructed barrel, usually made of cast-iron, fitted with a hammer which is forced down upon the cartridge by means of a tolerably powerful spring. The explosion frequently bursts the thin copper shell instead of driving the clay pellet out through the barrel, and fragments of the metal are driven into or through the palm of the hand, or into the large muscles on which the action of the thumb depends. Every surgeon knows that lock-jaw or tetanus is peculiarly liable to result from gun-shot wounds of the hands or feet, and many sad illustrations of the fact were given in the columns of the Wisconsin press about the time heretofore mentioned.

We learned from our correspondents that the sale of these toy-pistols was prohibited in several places, but in the large majority of our towns and cities no action was taken, and children were allowed to purchase the dangerous playthings and to run the risk of pain, mutillation and death in one of its most frightful forms for the advantage of thoughtless or unscrupulous men.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending October 28, 1882, indicate that dysentery and remittent fever have considerably decreased and that cholera morbus, rheumatism, typho-malarial fever, cholera infantum, diarrhœa and tonsillitis have decreased in area of prevalence. There was no marked increase in any of the diseases tabulated.

For the month of October, 1882, influenza, bronchitis, diarrhœa, cholera infantum, dysentery, and erysipelas seem to have been more prevalent, and remittent fever, diphtheria, intermittent fever, scarlet fever, and whooping-cough less prevalent than the average for October in the preceding five years. It will be seen that the most noticeable decrease is in the communicable diseases most to be dreaded in Michigan.

OBITUARY RECORD.—DIED, on October 13, 1882, CASIMIR JOSEPH DAVAINE in the 71st year of his age. Davaine is best known as having established the contagiousness of charbon from animal to man, and that the contagium depends upon bacteria. He also determined that the essential cause of difference between malignant pustule and other gangrenous diseases depended upon the presence of bacteria in the former disease which were capable of multiplying by inoculation.

—— Our English exchanges announce the death, in the 58th year of his age, of Mr. JOSEPH T. CLOVER, the well-known chloroformist to various London hospitals.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 30 TO NOVEMBER 6, 1882.

SPENCER, W. C., *Surgeon.*—In addition to his duties at Fort Snelling, Minn., to perform the duties of attending surgeon at Department Headquarters.—*S. O. 176, Department of Dakota, October* 24, 1882.

O'REILLY, ROBERT M., *Captain and Assistant Surgeon.*—Detailed member of board of officers to assemble at Washington, D. C., to examine into and report upon qualifications of candidates for superintendents of national cemeteries.—*S. O. 254, A. G. O., October* 31, 1882.

APPEL, AARON H., *First Lieutenant and Assistant Surgeon.*—Leave of absence extended two months.—*S. O. 255, A. G. O., November* 1, 1882.

GRAY, W. W., *Assistant Surgeon.*—Granted one month leave of absence on surgeon's certificate of disability, with permission to apply for an extension of five months.—*S. O. 103, Department of the South, October* 31, 1882.

BARNETT, RICHARDS, *Assistant Surgeon.*—Granted leave of absence for one month, with permission to apply for extension of five months.—*S. O. 202, Department of the East, November* 1, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked,

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLI. SATURDAY, NOVEMBER 18, 1882. NO. 21.

ORIGINAL LECTURES.

ON POTT'S DISEASE.

A Clinical Lecture, delivered at the Bellevue Hospital, New York.

BY LEWIS A. SAYRE, M.D.,

SURGEON TO THE HOSPITAL, AND PROFESSOR OF ORTHOPÆDIC SURGERY AND OF CLINICAL SURGERY IN BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

(Specially reported for THE MEDICAL NEWS.)

GENTLEMEN: This boy, aged thirteen years and nine months, was brought to me by Mr. Reynder (surgical instrument maker) about a week ago. He resides in Green Point, Long Island; his mother states that both parents and grandparents are healthy—she has, however, lost six chlldren, these dying from scarlet fever. The patient has always had good health; has had no disease except the measles and whooping-cough. On March 1, 1882, the patient received a severe fall upon the ice, and afterward complained of pain in the back. His mother took the boy to the Demilt Dispensary, and informs me that Dr. White said there was nothing the matter with him, and ordered a simple tincture. Three weeks after the fall, she noticed a projection over the dorsal vertebræ, and took him to Dr. Peer, of Green Point, who applied the plaster-of-Paris jacket as the child lay on the table; he, however, placed no padding to protect the vertebræ.

The boy was only able to wear the jacket for a few days, as it caused pain in the spinal column and impeded his respiration. Dr. Peer was again consulted, and he advised the mother to take the boy to Dr. Knight, of the New York Hospital for the Ruptured and Crippled, who applied a brace having shoulder-straps and fastenings around both thorax and abdomen (see Fig. 1). The mother states she has regularly

FIG. 1.

taken the boy to Dr. Knight, and followed instructions faithfully, but became dissatisfied with the treatment, as the deformity rapidly increased. She was then advised by a friend to consult Dr. Frank Hamilton, who advised her to return to Dr. Knight, as he knew of no one so well able to treat the case.

Dr. Gibney, of the New York Hospital for the Ruptured and Crippled, carried out the treatment recommended by Dr. Knight. The deformity, however, increasing, the mother called upon me with Mr. Reynder, at the same time showing me a report from the Hospital of the Ruptured and Crippled, from which I quote the following: "The discoveries, inventions, and mechanical appliances, in accordance with physiological laws and surgical science, we make available, but we carefully avoid compression of the respiratory organs by encasing them in plaster of Paris, or impeding the arterial circulation by compressing bands to the limbs. All such adventurous treatment is avoided in this hospital."

It is the first time I have seen this report, or I should have replied to it a long time ago. I therefore avail myself of this first opportunity, only regretting that I have not had time to call and see Drs. Knight and Gibney, and that I did not write to them and invite them to be present to-day, as they could then personally have seen the advantage of the plaster-of-Paris jacket, and that their own brace, and not the plaster jacket, was compressing the patient.

Now here is an excellent opportunity for testing the relative merits of the plaster-of-Paris jacket, which we will now apply, and point out the defects of the brace previously worn by the patient and which these gentlemen advised. The following measurements were now made with the brace upon the boy, the measurements being over the brace:

Over top of chest,	25⅝ inches.
Over nipple,	24⅝ "
Over umbilicus,	27½ "
Capacity of lungs measured by spirometer,	98 cubic "
Height,	4 feet 5⅝ "

The brace was then removed and the following measurements taken:

Over top of chest,	27¼ inches.
Over the nipple,	26⅛ "
Over the umbilicus,	24 "
Height,	4 feet 6⅛ "
Capacity of lungs,	116 cubic "

Upon a second trial of the spirometer, the boy blew so hard that the rubber pouch of the instrument burst, and thus unfortunately prevented the capacity of the lungs being taken after the application of the plaster jacket.

This is a practical illustration. We will now notice another point of objection to this brace. It is impossible to hold the instrument in position without tightening this muslin cloth to hold the irons in place. You then cause compression of the thorax. You also notice upon the sacrum and on either side of the ilium there are bruises, and again upon either side of the spine upon the spinous processes we find these bruises (see Fig. 2). It is impossible to fasten this brace securely and retain it in position without causing these lesions.

This practically shows you to what extent this brace compresses both thorax and abdomen, and to what extent circulation and respiration has been impeded (see Fig. 3). We will now place the child in such a

position that he can expand the lungs to the greatest possible extent, and we then apply the plaster-of-Paris jacket so that no excoriation of the body can take place, but all parts are equally and securely encased, avoiding pressure at any one point, and he can expire as freely as though the jacket were not worn. Some of the leading professors of Europe have used chloroform in order to secure greater extension, and have even attached weights to the heels to secure this result, but this is a most dangerous method.

FIG. 2.

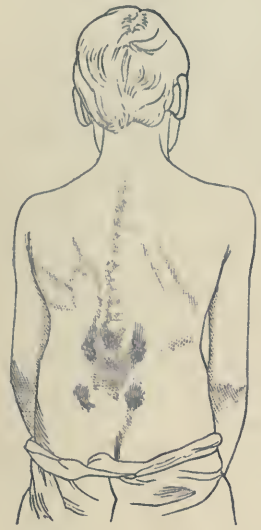

FIG. 3.

A leather collar was then placed around the patient's neck, with two straps on either side passing under the occiput and inferior maxilla to a suspended cross-bar, to which also were attached two straps passing under the arms. He was then carefully and gradually raised to his fullest height, at the same time leaving the feet firmly upon the ground. My rule is to raise the child within the limits of comfort, but not to cause a feeling of uneasiness or pain in the least degree.

We now apply to him a knitted shirt, manufactured by the Bickford Knitting Machine Co., 689 Broadway. The object is to have a perfectly elastic shirt. This fits the patient close to the skin at every point. Now, under this shirt anteriorly we place a folded cloth-pad, a little thicker over the sternum; then drawing the shirt firmly down between the legs, secure it there with a safety pin in order to keep it perfectly smooth.

Having previously prepared the bandages as follows: take cross-bar muslin, tearing it in strips three inches wide, rub the plaster of Paris well into the bandage, then roll it up carefully and keep it in a hermetically closed case or box to avoid absorption of moisture until ready for use; I use the dental plaster, which I find is the only plaster I can rely upon and which, generally speaking, sets as fast as applied; we now, as required, dip them into a basin containing sufficient water to cover them when standing on their ends; as soon as the air has escaped from the bandage it is then ready for use. You will here observe that I now place a pad on either side of the spinous process, to protect that eminence caused by disease; it is sometimes desirable to place a pad over the ilium, but in this case it is not necessary; the patient being now ready, my assistant applies the plaster-of-Paris bandages; you will notice as he draws the bandage around the body that I follow up with my hand rubbing the plaster into each band previously applied.

Now although the back is made as straight as it can well be by the suspension, yet the weight of the head still presses down upon the spinal column causing absorption of the vertebræ at the diseased point; it is necessary, therefore, to take the weight of the head from off the spine, and we now apply a *jury-mast;* this, as you observe, consists of two narrow cross-bars and side rods, from which passes a central rod, this central rod curving over the head of the patient, is supplemented with a small cross-bar; to the body of this light framework are fastened narrow strips of tin, perforated in both directions, the projecting burrs of which hold the instrument securely in the bandages. I have noticed that some physicians have perforated the tin in only one direction, thus allowing the instrument to slip on one side. The jury-mast being now shaped to fit the spine of the patient the plaster bandages are again applied over the instrument, encasing it firmly and securely in the centre of the jacket.

The patient should now be laid upon an air-bed; in taking the child down from his suspended position keep the body perfectly straight, for should you allow him to bend his back before the plaster has set, the application of the plaster jacket is of no avail and your work is lost.

We now draw out the pad which was placed over the thorax and abdomen under the shirt, and before the plaster has thoroughly set I commence with my fingers and thumbs to mould the jacket in over the spines of the ilium so as to widen the jacket out and take off the pressure upon the spinous processes, and at the same time to mould the jacket to fit the body; you thus shield the parts from pressure at any one point and equalize the pressure upon all parts of the trunk, and hold the child, as it were, from telescoping. It is now necessary to cut out some part of the jacket from under the arms, and also slightly in front of the thigh to allow him to flex the thigh. The plaster jacket now being dry, we proceed to take the weight of the head from off the spine by placing a light leathern collar with chin-piece attached around the neck of the patient; from this collar two small straps pass on either side of the head and are fastened to the cross-bar above the head, thus effectually relieving the spine from compression. And now, standing the boy upon the floor, you notice he can percuss upon the ground with his heels without percussing the vertebral column at all, and no pain is caused by the percussion. (The boy then stamped upon his heels without feeling the least pain, or indicating any by his countenance; the difference in the expression of his countenance being most marked.) This is a practical fact; it is not theory.

The old-fashioned brace had arm-pieces to lift the shoulders up, but that does not take off the pressure from the spine; when you take the pressure from the spinal column by elevating the head, the respiration is perfectly free, there is no compression of the thorax, and hence the advantage of the plaster-of-Paris jacket —compression of the parts is entirely avoided, while the vertebral column is relieved from the weight of the head as described.

This boy has had the jacket on him once before, but without effecting the desired result, simply because it was put on when he was lying down. I have tried all ways in which to apply the jacket and find the best way to apply it is when the patient is suspended.

CASE II.—This little boy was brought to me May 23, 1881. I here give you his history, as recorded on my books.

May 23, 1881.—Wm. Halsey Baird, age 2 years, 2 months, 23 Cottage street, Newark, N. J. Parents both healthy, have one other child which is strong and healthy, and is now 7 years of age.

Patient was always well until September, 1880, last,

when the child had a cold, and was taken to Dr. S. B. Dennis; as the child had never walked, the Doctor treated him by electricity, salt-water baths, massage, etc., for nine months; not improving, the child was taken to Dr. Blylie, who finding frequent priapism from contracted prepuce, attributed his want of muscular power to reflex irritation, and circumcised him. Not improving, however, in his ability to stand or creep, and complaining of constant stomach-ache; Dr. Blylie suspected trouble of the spine, and on examination found two small projections over the two lower dorsal spines, and advised the father to come to me.

On examination I found that the eleventh and twelfth dorsal vertebræ were quite prominent, the child was unable to stand. On laying him on his stomach across my knees and extending the spine, his breathing was more free, and he said he felt well; on pressing the head and sacrum towards each other it produced a spasm of his legs, and he cried severely with the pain induced by the pressure. Diagnosis: Spondylitis of the eleventh and twelfth dorsal vertebræ. No cause could be assigned for the difficulty.

Treatment: horizontal position, in wire cuirass.

May 31st.—Child was placed in a wire cuirass.

July 1.—Child has improved since being placed in the cuirass; to-day suspended him and applied plaster-of-Paris jacket.

4th.—Child stood up to-day for the first time.

Aug. 8.—Child has been perfectly comfortable since the jacket was applied.

Nov. 30.—Child has been in excellent health since last date; has been walking for the past five or six weeks; the jacket was cut down about two weeks ago, because it was too tight, and secured by a roller bandage; child has grown in every way. I afterwards applied a new jacket.

April 4, 1882.—Five weeks ago the child complained of the jacket being too tight, the father then cut it down and secured it with a roller bandage; has been perfectly well all the winter, and has been walking all the time. When the jacket was removed the child could stand and walk without any pain or support. There is no pain on compression or concussion; a new jacket was then applied as a protection against relapse.

Sept. 18.—Child is perfectly well, and no perceptible deformity of the spine, with the exception of a slight fulness hardly observable; can run and jump as well as any child.

Weighs 31½ pounds, and measures 3 feet and ¼ inch in height. (The child was then stripped and placed before the class.)

Now here (pointing to the child) by carefully looking you can see a slight shadow and fulness just at the lower dorsal vertebræ; it is, however, hardly noticeable.

Dr. H. Smith, of Philadelphia, states that no case of Pott's disease was ever cured without deformity. If you let the case go on too far, of course you will get deformity; if absorption of the vertebræ has taken place, there is a deformity that will last a life-time, but the deformity is not the disease, it is the evidence of the disease; the disease must have existed a long time before the deformity occurred.

Now your duty as a skilful practitioner is to diagnosticate the disease in its incipient stage; and if you will carefully spell out the symptoms, you will diagnosticate the disease before the deformity has occurred; and if you apply the treatment in that stage, you will cure the disease without deformity. I have found the average time of cure to be effected in from two to two and a half years, some being cured at an earlier, and some at a later date. Now compare these statistics with those of past years, where the patient was confined to his bed for ten or twelve years, and if they ever were cured it was with a deformity.

Now here is a boy, you observe, who has been cured almost without any deformity at all in less than eighteen months; this child (here placing a penny on the floor) stoops over and picks up a penny from the floor as well as any child; you will see those children who are suffering from this disease, when attempting to pick anything up from the floor, will squat down bending sideways, and avoid bending the spine, which they would not do if free from disease of the vertebræ. When we have cured the child of the disease, we cut the jacket down and allow him to wear it as a corset for some months longer, simply as a protection against a relapse (see Fig. 4).

FIG. 4.

Mr. Howard Marsh, of St. Bartholomew's Hospital, London, in an article written by him in the *British Medical Journal* of October 12, 1881, remarks, "that although the plaster jacket is the best treatment for adults, it is an absolute impossibility to apply it to a child under nine years of age, because they have not sufficient pelvis to support the jacket." I have not had time to answer this remark, but of a great number of children below the age of nine years who have had the plaster jacket applied, the greater number have been cured with but slight deformity; and I am waiting to bring together a number of those who have been cured by this means, and have them photographed in a group. I have not been able to get many cases of children suffering from this disease who can stand up or run about when brought to me because they were too young or were paralyzed, and therefore could not take their photograph before the application of the jacket; we have only the artist then to rely upon for a picture of the child's condition, and people will scarcely credit his representations, no matter how good an artist he may be. You can, however, verify these facts in your own practice. If the child is too young, and has no pelvis to which you can apply the jacket, you must then place it in a wire cuirass for a few months; the child can in this manner be carried out-doors to secure the benefit of the fresh air.

Mr. Marsh states that a child being only as large around the hips as at the umbilicus, the plaster will slip off; now here is a practical case to illustrate this point: the plaster jacket worn by this child (measuring

jacket before class) is exactly 21 inches around the umbilicus, and it is also exactly 21 inches around the hips; but, as you observe, it has been moulded in when wet, over the crest of the ilium, and it is exactly 21 inches at that point, thus proving Mr. Marsh's measurement correct. Now in order to obviate this difficulty, I mould the jacket in when wet, over the crests of the ilium and secure a shoulder for the jacket, at the same time allowing greater distention of the abdomen. I also, as you observe, have moulded this jacket in *before* the ilium antero-posteriorly, thus increasing the width of the jacket laterally, which is just the opposite to the moulding *above* the ilium, and thus the jacket is held firmly upon the child, the measurements still remaining just the same, namely 21 inches.

CASE III.—Now here is a little boy who, had he been treated in the proper manner, would not be in his present condition, but the father of the child, Mr. Dunn, will give you the history of the case. Statement made by Mr. Dunn: "We discovered that something was the matter with the child some seven weeks before we could see anything outwardly; especially we noticed it when the child would stoop down; I sent for a physician, and he decided something was the matter with his spine; he sent to New York to get a brace to support the spine. In two weeks time after wearing the brace the projection upon the spine was almost as distinct as it is now. At the time of the application of the brace there were no appearances of this projection upon the spine."

This statement does not surprise me in the least; if you bind the child together how can it grow; it would make it grow deformed with these straps over the shoulders and around the body; they will crush the vertebræ together and increase the rapidity of the growing deformity. This child was afterwards put into a hammock and the plaster jacket applied as the child lay on his stomach, according to the method of Mr. Davy of London, which, you will observe, has given a backward curve to the spine; he cannot percuss upon his heels, as you see.

Now this child has been under treatment for two years and you see how great the deformity of the spine is at the present time. Compare it with that of the previous case, who has now been under treatment but eighteen months, and yet is completely cured and without deformity. A simple glance will suffice to show how far the superiority of the plaster-of-Paris jacket, when properly applied in the treatment of spondylitis, is over any brace that has yet been invented.

At a future time I will bring before you the first case presented here to-day; we will then note the boy's condition as treated by the application of the plaster-of-Paris jacket.

ORIGINAL ARTICLES.

IS TUBERCULOSIS A PARASITIC DISEASE?

FOURTH PAPER.

BY GEORGE M. STERNBERG, M.D.,
SURGEON, U. S. A.

BEFORE proceeding to give an account of the results obtained in my inoculation experiments with tuberculous sputum, I beg to be indulged in a few remarks with reference to the value of photography in the study of micro-organisms. These remarks are suggested by the wood-cut (figure 6) in my last paper, which is copied from a photo-micrograph of *Bacillus anthracis* (amplification 500 diameters).

This figure illustrates very well the difficulty of reproducing a photo-micrograph, satisfactorily upon wood; and, also, the fact that the value of sun-pictures of micro-organisms depends to a certain extent upon whether they are to be subjected to the scrutiny of a trained or untrained eye.

Those who are familiar with *Bacillus anthracis* from personal observation or from drawings will scarcely recognize the amorphous granules and irregular linear figures in this wood-cut, as the spores and rods of the bacillus in question. The central filament is, however, very well drawn, and it was for this especially that this photo-micrograph was selected.

It is well-known that an expert microscopist, when at work, pays very little attention to extraneous objects in the field, to dust-specks on the eye-piece, etc., while a novice is very apt to have his attention particularly attracted by these things and to overlook the particular object which we desire to show him. So an art connoisseur looking at a time-worn picture is able to exclude the fissures and stains, and to his mental vision the work of the master is revealed in all its perfection of form and color, while for the uneducated eye there is no beauty in the scarred and dingy canvas.

The focal range of the high-power objectives used in photographing bacterial organisms is so short that all of the objects in the field of view can not be brought into proper focus at the same time, even when these are attached to the thin glass covers, as is customary; for all are not in exactly the same plane, and there is a certain variation in the diameter of these minute organisms which causes the best focal adjustment for one, to be not the best for another. The aim of the operator is, therefore, to secure the most satisfactory general results, and the expert in looking at the picture will fix his attention upon the objects which are well-defined, recognizing the fact that some are a little out of focus and therefore more or less distorted.

In view of their difficulties I am inclined to think that it is better to place carefully executed drawings, made by the observer, in the hands of the wood-engraver, rather than photo-micrographs.

By the heliotype process the latter can be reproduced with great fidelity; but owing to the expense of this process this mode of illustration is not available for journal articles. The main value of photo-micrographs consists in the fact that they show to an expert that the observer who thus illustrates his work has sufficient technical skill in the manipulation of high powers and in preparing, staining, and photographing the organisms which he describes, to insure his readers that they are not the victims of gross mistakes, such as have more than once passed current in medical literature as the result of a facile pen in the hands of an indifferent microscopist. Beyond this, photo-micrographs possess an especial value for the observer himself. They are his memoranda of what he has seen, and enable him to compare organisms observed at different times, to detect slight morphological differences, various modes of grouping, etc. I take this opportunity, also, for correcting a typographical error in my last

paper. On page 312, second column, third line from bottom, for "spontaneous *fusion*," read "spontaneous *fission*."

In my third paper (page 312) I report a negative result in three out of six specimens of tuberculous sputum furnished me (Aug. 10) by Prof. Hirschfelder from patients in the City and County Hospital, San Francisco. A subsequent examination by Dr. H. and myself demonstrated the presence of Koch's bacillus in the sputum of these patients. One of these cases has since terminated fatally, and I have in my possession a portion of the lung preserved in alcohol. The tubercular nodules in this lung contain the bacillus in abundance.

A more ready way of demonstrating the bacillus in such material than the somewhat tedious process of making sections, staining, and mounting in balsam, is to make a fresh section, pick out a tubercular nodule with a clean instrument, crush it upon a thin glass cover in a drop of distilled water, dry by gentle heat, and finally stain by Ehrlich's method.

Experiments upon Animals.

Experiment No. 3, July 29[1].—The following animals were inoculated with the sputum of a tuberculous patient (diagnosis by Prof. Hirschfelder, to whom I am indebted for the material): One pup, four weeks old; one half-grown rabbit (white); two smaller rabbits (spotted); one small guinea-pig. My report of the microscopical examination of the material used in these experiments will be found on page 311 of this journal and is as follows: "A few bacilli were seen by Baumgarten's method which possibly respond to the test-failure to stain by methyl violet after treatment with solution of potash—but the result is not considered satisfactory, as the bacilli referred to appear to have less color than others in the same preparation, because of their smaller diameter, rather than to be entirely without color." At the present writing I no longer doubt the presence of Koch's bacilli in the material referred to, and am convinced that the demonstration would have been made at the time if I had been familiar with Ehrlich's method.

The pup used in this experiment presented no signs of ill-health up to the time it was killed (October 11th). It had, however, a local ulcer at the point of inoculation (the side of the neck) which did not entirely heal until a short time before the animal was sacrificed. Post-mortem examination did not reveal anything abnormal in the lungs, spleen, or liver. The animal was fat and no tubercles were discovered in the organs named, or the serous membranes.

The half-grown white rabbit was killed October 8. A few miliary tubercles (?) of small size were founds in the lungs of this animal. These did not contain Koch's bacillus. Lymphatic glands from the axilla, examined by Ehrlich's method, also gave a negative result. The animal was fat and all the organs appeared to be normal with the exception of a number of minute tubercles scattered through the lungs as stated.

[1] For an account of experiments 1 and 2 of this series, see THE MEDICAL NEWS, page 311.

One of the small spotted rabbits was killed October 9. This animal was in good condition and had grown very much since the date of inoculation. *The lungs contained groups of tubercular nodules of considerable size, and the bacillus of Koch was found in these by the method of Ehrlich.*

The other spotted rabbit has been lost sight of, and has possibly been used in one of my septicæmia experiments.

The small guinea-pig was killed October 9. The animal had grown considerably, and was in apparent good health. There was still an open ulcer, the size of a silver five-cent piece, at the point of inoculation. The lymphatic glands in the axilla, near point of inoculation, were greatly enlarged. *The lungs, liver, and spleen contained numerous tubercles, and the presence of Koch's bacillus was demonstrated in these organs and in the enlarged lymphatic glands.*

Experiment No. 4, August 12.—Inoculated the following named animals with tuberculous sputum from Dr. Brook's case. This patient was in the last stages of consumption, and has since died. The sputum contained an abundance of Koch's bacilli. (*Vide* MEDICAL NEWS, page 312.) One pup, six weeks old; one large spotted rabbit; one small spotted rabbit; one large male guinea-pig.

The small rabbit died at the end of three days. The lungs, liver, spleen, kidneys, and brain were normal in appearance, and the remark was made at the time that the animal probably died from some cause independent of the injection. Its colon was in a congested condition. No bacilli were found in lymphatic glands from the vicinity of point of inoculation.

The guinea-pig died August 24. There was a considerable collection of fluid pus at the point of inoculation, which was found to contain a few of Koch's bacilli. The animal was quite fat; its liver was leather-colored and loaded with fat; the spleen was slightly enlarged and dark-colored; lungs normal. No tubercles found in any of the organs. It is the writer's opinion that the animal died of septic poisoning (septic toxæmia due to chemical products of decomposition) resulting from the presence of the collection of putrid pus in the subcutaneous connective tissue.

The large spotted rabbit remained in good flesh, and in apparent good health up to the time it was killed, October 7. An ulcer, of small size, was discovered at the point of inoculation a few days after the operation. Pus from this ulcer examined September 14, contained Koch's bacilli. The lymphatic glands in the vicinity became enlarged, and upon making an incision into one of them (September 18) a small quantity of cheesy pus escaped. This was carefully examined for the bacillus, by Ehrlich's method, with a negative result. The absence of the bacillus was also proved by two culture-experiments in which sterilized blood-serum was inoculated with a little of this cheesy material. No development occurred. This rabbit remained in good condition, and in apparent good health up to the time it was killed, October 7. Upon post-mortem examination a collection of cheesy pus was found at the point of inoculation, and an enlarged

lymphatic gland in the vicinity contained material of the same kind. One small group of tubercles was found in the lungs. Koch's bacilli were not found in these or in the contents of the enlarged gland.

The dog was killed October 12, just two months after inoculation. It had an open ulcer at the point of inoculation for several weeks, but this had cicatrized a short time before its death. It remained active and playful, and in good flesh up to the date mentioned. Upon post-mortem examination two enlarged glands were found in the axilla, near point of inoculation, and *contained an abundance of Koch's bacilli.* The spleen contained numerous miliary tubercles, but no bacilli were found in these. The lungs were normal.

Experiment No. 5, August 14.—Inoculated two small rabbits with sputum of tuberculous patient (case in my own practice, *vide* MEDICAL NEWS, page 312) demonstrated, by Ehrlich's method, to contain Koch's bacilli.

One of the rabbits was injected with normal saliva (my own) October 3, and died of septicæmia on the 6th. Its lungs contained numerous groups of tubercles, but repeated examination has failed to demonstrate the presence of the bacilli in these.

The other rabbit was killed September 25. The lungs were found to contain *a few tubercles in which Koch's bacilli were found.* Other organs normal, with exception of two cysts in the liver containing the ova of a parasite (species ?) very often found in this situation in the rabbit.

Two culture-tubes containing gelatinized blood-serum, sterilized by Koch's method, were inoculated with tubercular material from the lungs of the rabbit last mentioned. These were placed in the culture oven at 100° Fah. No development occurred in one of these tubes, but in the other microscopical examination made at the end of twenty days showed that an abundant development of Koch's bacilli had taken place. As pointed out by Koch this development takes place *in situ*, the bacilli not penetrating the gelatinized blood-serum, and nót extending materially upon the surface. I have several other cultures started, and in each case with the same result, so far as the naked-eye appearance is concerned. The blood-serum remains transparent and free from other micro-organisms; the bits of tubercular material remain upon its surface; and the only change apparent is a slight lateral extension (?) and increased opacity, or rather a faint brownish color in place of the pearly white lustre of the original material.

Experiment No. 6, August 24.—Inoculated a small rabbit with pus from large guinea-pig (subject of experiment No. 4). This pus, which came from an abscess at point of inoculation, was found by Ehrlich's method to contain Koch's bacilli. The rabbit remained in apparent good health, and in good condition up to October 11th, at which date it was killed. A single transparent nodule the size of a pin's head was found upon the surface of one lung. This examined at once by Ehrlich's method, was found to contain giant cells and the bacillus of Koch. The bacillus was also found in a collection of cheesy pus at the site of inoculation and in an enlarged lymphatic gland from the vicinity (axilla). This enlarged gland contained numerous white nodules which contained giant cells and the bacilli in question.

The writer proposes to leave those who have followed him thus far to judge for themselves as to the value of the experimental evidence above recorded. Having undertaken to repeat the experiments of Koch, he does not wish to be hampered by any premature expression of opinion, as the most important portion of the experimental inquiry remains to be made, viz.: the cultivation of the bacillus through successive generations, (a fortnight is required for a single culture); inoculation experiments with pure cultures; and, side by side with these, inoculation experiments with material from various sources which is free from the bacillus.

But our promises are made as to the completion of this undertaking which involves a considerable expenditure of time, and a certain amount of money, items which are of some consequence when they are drawn from the resources of a single individual. Fortunately Koch has had a liberal government at his back and his experiments may be counted by hundreds, where those of his humble followers can not be by scores. Still the observations and experiments recorded in these papers have been no inconsiderable tax upon the writer's time during the past four or five months, and, as one engaged in interrogating nature by the experimental method, has always a sufficient number of problems before him in which he can take the more agreeable *role* of pioneer, he feels scracely equal at present to the labor involved in following to the end the path which has been trodden by this indefatigable explorer. Nor are my facilities for doing this work such as I would wish. A culture-chamber kept in operation, night and day for many months, by means of *an alcohol lamp* (no gas at military posts), is not only expensive but difficult to regulate. Rabbits and guinea-pigs are not always to be had in the San Francisco markets, and the price demanded for them indicates that they are offered for sale as pets rather than for the table, or for scientific purposes.

Perhaps, then, some one more fortunately situated will take up this matter where I leave it for the present. Or, if we wait a little, it may be that some one of the many well-known experimentalists in Europe, under government auspices, will undertake to repeat Koch's experiments, and we will then have the confirmation, as we have had the exploratory investigation, without putting our hands in our pockets, and, as heretofore, will have the calm satisfaction of knowing that we receive our scientific information at second-hand.

STRYCHNIA AS AN ANTIDOTE IN CHLORAL POISONING.

BY J. T. MOORE, M.D.,
OF TILSONBURG, ONTARIO, CANADA.

IN the *American Journal of Medical Sciences* for April, 1882, page 608, under the heading of Med-

ical Jurisprudence and Toxicology, I find an article from eminent authority relating to the antagonism of strychnia and chloral, the correctness of which I cannot verify from past experience (at least some of the conclusions). I do not for a moment dispute the theory as arrived at by experiments on rabbits or other small or cold-blooded animals, but I state that experience teaches us more truthfully and practically when circumstances arise by which conclusions may be drawn from actual experiment upon the human organism. To show the power which large toxic doses of strychnia exert in controlling and antagonizing acute chloralism, I cannot illustrate better than to give report of following case:

CASE I.—On May 30, 1882, at 10.30, A.M., I was requested by Dr. Soper to meet him in consultation to see O. B., aged about 50, spare build, and prematurely aged in appearance. Upon arriving, I elicited the following information from Dr. Soper, who first saw the patient about thirty minutes before I arrived. About midnight the patient had left in his room an 8-ounce mixture, containing 1 drachm of chloral hydrate to the ounce. He was on a visit to his brother, who lives in town, and stated that he had been in the habit of using a similar mixture to relieve pain and produce sleep; however, in the morning, when they went to call him, he was in a profound sleep, from which they could not rouse him. They concluded to allow him to sleep, which he did until 10 o'clock, A.M., when they became alarmed and sent for a physician. He had taken 5 ounces of the mixture, which represented 300 grains of chloral; present condition, surface cold, heart's action very rapid, feeble, and irregular, missing about every fourth beat; respiration labored; pupils totally insensible to light; conjunctiva intensely congested, totally insensible to all external impressions; reflex excitability totally *nil.*; tongue paralyzed, so that he had to be rolled well forward to prevent it falling back into throat and impeding respiration; mucous râles of large character in both lungs, and considerable rumbling in stomach and bowels. His condition was such that we could not give anything *per via nat.* The time, about six to eight hours, since taking the dose rendered the stomach-pump of no assistance. We concluded the only chance left was hypodermic medication; consequently I threw into the right arm 5 minims of the pharmaceutical solution of liquor strychniæ, diluted with 5 minims of water; in ten minutes the pulse was stronger, slower, and more regular; it then registered 116; thirty minutes later it had risen to 144, weak and flabby again; threw into left arm 7 minims liq. strych., diluted to 14 minims; ten minutes later, pulse 120, stronger, and more regular than before; also, gave enema of two ounces of brandy in half a pint of milk; respiration much easier. Professional engagements calling me away, Dr. Soper watched him as he gradually improved, pulse falling and becoming stronger, and respiration becoming more natural, until 2 P.M., when the symptoms seemed more stationary. At 3 P.M. Dr. Soper threw into the left arm 6 minims of strychnia, as before. I called at 3.30, and found the patient bolstered up in bed, taking cognizance of surrounding objects in a bewildered manner, pulse 68, strong, perfectly regular, and from this time the patient steadily improved, and at 7 P.M. was able to get up, dress, and walk about the house, asking for more chloral; passed water freely at 7.45. The following morning he rode thirteen miles in a stage coach to his home, where the following night he succeeded in getting hold of a mixture containing 700 grains of chloral, which had been hidden from him, and drank the whole of it, dying about two hours after.

CASE 2.—Some three years ago I had a valuable dog poisoned with strychnia. Every symptom strongly pointed towards speedy death. I used hypodermically a saturated solution of chloral hydrate, carrying it independent of quantity to total hypnotism; the result was, life was saved and a good recovery made, although partial paralysis of hind quarters existed for a couple of weeks; temporary paralysis of bladder and bowels passed off in twenty-four hours.

From the above cases, I should not feel justified in wasting valuable time in trying other experiments, as I believe, unless the quantity of either poison taken be not largely in excess of that which the animal economy can eliminate in a reasonable time, they may be antagonized the one by the other.

SODIUM BICARBONATE IN THE TREATMENT OF ACUTE TONSILLITIS.

BY E. STUVER, B. SC., M. D.,
OF RAWLINS, WYOMING TERRITORY.

THE routine treatment of acute tonsillitis by means of gargles, inhalations of medicated vapors, leeches, poultices, etc., even in the most skilful and judicious hands, furnishes at best but very unsatisfactory results.

Flint, in his *Principles and Practice of Medicine* fourth edition, page 396, says, "Acute tonsillitis generally ends in suppuration; an abscess forms and purulent matter sometimes fetid, and nauseous to the taste is discharged after a period varying in different cases from two to ten days."

The disease, while not involving danger to life, except in those rare cases in which œdema of the glottis supervenes, is nevertheless, owing to the pain and difficulty in deglutition, a very distressing affection.

In view of the above-indicated results of treatment, together with the fact that the most eminent and popular authorities, do not allude to the beneficial effects derived from sodium bicarbonate in the treatment of this disease, and in order that the attention of the profession may be directed to the subject, and the efficiency of the remedy thoroughly tested, the following case is reported:

Mrs. D., æt. about 27 years, a strong healthy woman, has for years been subject to very severe attacks of acute tonsillitis, which cause intense suffering, and though always energetically treated by poultices, gargles, scarifications, etc., have invariably resulted in suppuration and discharge of pus. She has had four or five attacks of this kind previous to the one under consideration.

On September 7, 1882, had a chill, followed by

fever, pain in the head, and general muscular soreness. On the following day the tonsils began to enlarge. A gargle was obtained from another physician, but had no effect whatever in checking the progress of the disease. On September 9, about 6 P.M., was called to see the patient, and found her suffering very severe pain in the tonsils, which on inspection were found to be much enlarged, the right more than the left, of a dark livid hue, and covered with a white, easily detachable exudation; voice greatly impaired, and attempts at speaking or deglutition very painful, and nothing except small quantities of liquid could be swallowed.

Temperature 101° (Kew); pulse 100. Gave a gargle of potassium chlorate and tincture of chloride of iron in aqueous solution, and ordered it to be used at short intervals. Called at 9 o'clock P.M., but found no improvement in the symptoms.

Resort was then had to sodium bicarbonate, which was thoroughly applied to the affected parts, in *powder form*, by means of an insufflator. The applications caused some retching, and considerable material was ejected with manifest relief. The nurse was then instructed how to make the applications and directed to apply the remedy every hour during the night, which she faithfully did.

Sept. 10.—9 A.M. Temperature 99°; pulse 104. 8.30 P.M. Temperature 100°; pulse 90.

Rested very well during the night and this morning, throat is feeling much better, there being but little pain in, and considerable diminution of size of tonsils, also decided improvement of voice. Gave instead of the sodium bicarbonate an application of the following, viz.:

℞.—Acidi Tannici,	. . . . 3i.
Iodoformi,	. . . . . grs. x.—M.

But this increased the pain and was not repeated. Continued the sodium bicarbonate applications at short intervals during the day, and in the evening found the patient much improved and highly elated at the prospect of escaping from her usual severe suffering.

11th.—9 A.M. Temperature 99°; pulse 86.

Rested well during the night, and is greatly improved in every respect; pain almost entirely gone; swelling greatly diminished, and deglutition but little interfered with. The recovery would have been speedy and uninterrupted had the patient not injudiciously exposed herself before fully recovered, and brought on a return of the symptoms, which, however, speedily yielded to the former treatment without suppuration or any other unpleasant complication.

The remedy should be applied in *powder form*, by means of insufflation, the solution not having the same beneficial effect as demonstrated in a subsequent case.

MEDICAL PROGRESS.

Inflammation, Suppuration, and Ulceration of the Tongue.—Mr. Bryant read a paper on this subat the meeting of the Medical Society of London held October 23d. He detailed examples of abscess due to injury as well as to idiopathic causes, and showed how this affection has a tendency to get well, and more particularly after an early puncture. He recorded two examples of hydatid of the tongue. The subject of chronic superficial glossitis then received attention, and it was illustrated by cases as well as by a preparation. Superficial ulcerations were then described, and some good examples quoted of the simple dyspeptic ulcer. Ulcers due to local irritation were then described, and cases quoted, in one of which the ulcer had existed for two years, and had been mistaken for a cancer. Deep-seated ulcerations were fully considered, and the differences between the syphilitic, epitheliomatous, and tubercular forms dwelt upon. The tendency for the chronic syphilitic disease of a tongue to pass into cancer was emphasized, and the danger of not fully recognizing the tendency pointed out. The connection between epithelial cancer of the tongue and ichthyosis was demonstrated, and the local character of the cancer noticed. The necessity for the early removal of a cancerous tongue was strongly enunciated, and some good cases quoted in which a long immunity from the disease, if not a cure, had been obtained. The different modes of operation were then discussed, and statistics given of operations, in which the mortality as a whole from the operation was shown to be about ten per cent. Amongst the advantages of the operation was advanced the fact that when a cure does not take place great comfort is given, and that a return of the disease is more likely to occur in the glands of the neck than in the tongue itself. Time not permitting of some remarks being made on tubercular disease of the tongue, it was deferred to another occasion. The paper was illustrated by drawings and preparations.—*Lancet*, Oct. 28, 1882.

Treatment of Cutaneous Diseases by Scarifications.—After diligent study of almost all the cutaneous maladies in which linear scarifications have been resorted to, and after comparing the results obtained from this method with those which have followed the employment of other medical or surgical means—availing himself, moreover, not only of the opinions expressed by the most competent authorities, but also of his own observations in numerous cases—V. Bartoszewicz (*Th. de Paris*, 1882) has arrived at the conviction that in the treatment of many skin diseases, the above-named procedure must be regarded as more prompt and satisfactory in its consequences than any other previously employed.

A rapid improvement and speedy cure, without liability to a return of the disease; white, thin, and smooth cicatrices—such are the advantages offered by this mode of treatment.

In no form of disease, however, are those advantages at once so strikingly apparent and of such capital importance as in the most dangerous, most destructive, and most disfiguring affection of its class—*lupus vorax*.

Not unfrequently, three or four scarifications are sufficent to arrest the progress of the complaint, and after a few months of treatment the cure is complete, the resulting cicatrices being productive of much less defomity than those left in similar cases after any other process.

He is aware that even this method is not without its disagreeable features. The pain it occasions is sometimes quite severe, a troublesome amount of hemorrhage may be produced, and the treatment, now and then, is necessarily protracted, involving a frequent repetition of the process. Yet its incontestable advantages, in the cases to which it is applicable, are so predominant and so far outweigh those derived from any other source, that linear scarifications must take the highest rank among the means of combating many cutaneous disorders, especially those hitherto most difficult of cure.—*Journal of Cutaneous and Venereal Diseases*, November, 1882.

A New Procedure for Making Compressed Sponge Antiseptic.—Notwithstanding the danger of infection from the use of sponges in uterine therapeutics, they are often a very convenient and useful means in the treatment of metritis of long duration, encouraging resorption, acting as a tonic upon a flabby and weak uterus, and more effective under these indications than either tupelo, laminaria, or mechanical dilators. Iodoform was the substance which occurred to Dr. Fraenkel's mind (*Centralb. f. Gynäkol.*, August 12, 1882) as a means of rendering sponge tents aseptic. Two patients were chosen for the experiment—one a multipara with a soft, flabby, easily bleeding uterus; the other a primipara, forty-two years of age, with chronic hyperplastic metritis. The patients were placed in the knee-elbow position, *the uterine cavity* was washed out with a warm three-per cent. solution of carbolic acid, introduced through a uterine catheter, and the tents were next adjusted. They were made of compressed sponge, prepared with cerate, rubbed with salicylated cotton, and were then covered with a thick coating of pulverized iodoform. After they had been introduced, a quantity of iodoformed gauze was placed in the vagina. Violent expulsive pains followed this operation, but no fever. The tents were removed after eighteen or twenty hours, and no bad odor was present. In two other cases the uterus was injected in a similar manner, and in the first of these a further injection of a syringeful of liquor ferri sesquichloridi was made with a Braun's syringe. In the second a like quantity of tincture of iodine was injected. Neither of the patients suffered any evil consequences from this treatment. [We do not think that the author's method of injecting the uterine cavity is to be recommended. With the patient in the knee-elbow position, there was the force of gravity, in addition to the injection force, which might be expected to impel the liquid into the Fallopian tubes, and thence into the peritoneal cavity. That no damage was sustained proves only that these particular patients were capable of enduring heroic treatment.]—*New York Medical Journal*, Nov. 1882.

Ovariotomy; Closely Adherent Intestine; Recovery.—Mr. Roe reports the following case, occurring under the care of Mr. Sidney Jones at St. Thomas's Hospital: Emily B., a married woman, aged 30, was admitted on November 18, 1881. She stated that her father was living and healthy, that her mother died of bronchitis, and that there was no history in the family of tumors. She had never been strong, but had never had any particular illness; she had been married twelve months, but had not had a child. Her present illness began, about six or seven months ago, with pain in the lower part of the abdomen, and she then first noticed a swelling in that position; this swelling gradually increased, but pain ceased about the beginning of November. She had had pain and difficulty in passing motions and urine about three months earlier; but this had also disappeared. Since the beginning of this illness she had menstruated every fortnight; before she was always regular. On admission, the abdomen was considerably distended, and the girth at the umbilicus was 35½ inches. The enlargement was caused by a firm, tense, elastic tumor, softer just over the umbilicus; the surface was smooth, and there were no nodules. The tumor was of rounded form, and occupied more of the left than the right side of the abdomen; it was slightly movable. The percussion was dull over the tumor, with a resonant note in the flanks. A distinct thrill could be felt through the tumor. The urine, of specific gravity 1014, contained no albumen.

November 25th. Since the patient had been in the surgical ward she had had no pain in the tumor. On the first evening the temperature was 100° Fahr.; since then it had not been above 99° Fahr. On this day the patient was operated on by Mr. Sidney Jones. A median incision was made through the abdominal walls; the peritoneum cut through, and the tumor exposed; the incision was prolonged upwards above the umbilicus; the tumor was tapped, which reduced the bulk of it considerably; some slight adhesions were detached by the finger, but in one place a loop of intestine was somewhat firmly adherent. A ligature was passed around the attachment, which was then divided. The uterus was also found adhering to the tumor: the connection was ligatured and divided. The pedicle of the tumor, which was rather broad, was perforated and tied by a double ligature, divided, and returned into the abdomen. The edges of the incision were sutured by deep and superficial stitches. The tumor weighed over eight pounds, and more than six pounds of fluid ran off from it. The operation was conducted antiseptically. The same evening, after the operation, the patient was fairly comfortable, and breathing easily. The pulse was 84, and the temperature 98.4°.

The patient continued to improve, being troubled only by a tendency to constipation. She left the hospital well on January 3, 1882.—*British Medical Journal*, October 28, 1882.

Treatment of Anal Fistulæ by the Elastic Ligature.—At the meeting of the Société de Chirurgie, held September 11, M. Terrier presented some observations on the treatment of fistula in ano by the elastic ligature. He advises the use of the elastic ligature if the fistulæ are only of short extent, if they result from an acute inflammation, and if the bridge of tissue to be divided is not very thick. Occasionally the ligature causes acute pain; the division is very slowly accomplished, and the ligature must be occasionally tightened up. If the fistula is of longer extent, with diverticula, he often employs the linear écraseur; he passes first a thread through the fistula and then the chain of the écraseur.

Chassaignac advocates the passage first of a drainage-tube through the course of the fistula, and allows it to remain several days, and then employs the écraseur to divide the fistula. When vegetations are present they should be cauterized with the thermo-cautery.—*Gazette Hebdomadaire*, October 20, 1882.

Spontaneous Cure of Vesico-vaginal Fistulæ.—Dr. Julius Heyne (*Inaug. Dissertation*, Halle, 1881) writes that the prophylaxis of vesico-vaginal fistulæ depends mostly on careful watching of the bladder during labor, emptying it when necessary, and not allowing too long-continued pressure of the head in one position. After delivery, careful treatment of any tendency to cystitis, and antiseptic, and if necessary, cauterizing, treatment of any ulcerations or sloughs in the vagina. In case a fistula occurs, the first question is when to begin treatment. Here authorities differ greatly, but the author believes that, in cases where the lochia are normal and there is no inflammatory action going on, the sooner the fistula is treated the better. This is perhaps the strongest point in this method. Many ways have been proposed for inducing the spontaneous cure of fistulæ. The most common are drainage of the bladder by permanent catheterization and tampon of the vagina. Substances of all sorts have been used for tampons. The position of the patient has also been considered of great importance. In contradiction of some of the best authorities, the author claims that the *vaginal tampon is of no use*. Its alleged use is, first, to keep the edges of the fistula together. This it does not do, but, on the contrary, separates them. Second, it causes great disturbance to the patient and irritation of

the vagina. Third, it does not prevent the flow of urine through the fistula, but soaks it up or backs it up in the vagina, and thus causes catarrh of the vagina and bladder, and an unhealthy action in the wound. He believes it is best to *leave the vagina empty*. In the second place, his plan for drainage is by a rubber tube inserted through the urethra, not *into* the bladder, but just *to* it, so that the bladder may be permanently drained without having a catheter retained in it. In case of a simple torn fistula, discovered early, this is all that it would be necessary to do. In case of a fistula occurring later, and caused by the sloughing out of a piece of the vaginal wall, the vagina and uterus must be washed out daily with disinfecting solutions and the edges of the fistula touched with stimulants to promote granulation. Two of Prof. Fritsch's cases are narrated in detail to show the advantages of this practice. One was an old case in which several operations had been previously done, the other was a fresh case.

The author concludes as follows: If a fistula is discovered while patient is in the lying-in bed.

The bladder is drained.

The vagina is scrupulously cleansed, but not tamponed.—*Amer. Journ. of Obstet.*, Nov. 1882.

PATHOLOGY OF URÆMIA.—HLAWA and THOMAYER have endeavored to advance our knowledge as to whether uræmia in nephritis is accompanied by any definite anatomical changes, and, if so, what causal connection there might be between these alterations and the symptoms of uræmia. Accordingly, investigations were made by them on twenty-two cases of nephritis, some of which had, and some had not, shown symptoms of uræmia during life; and they have put on record the results (*Wiener Med. Wochenschrift*, No. 39). In all the cases of uræmia the kidneys showed a more or less considerable (generally quite recent) small-celled infiltration; this was not the case with the rest. The infiltration of small cells existed in the neighborhood of the Malpighian bodies, and more especially at that part where the afferent and efferent vessels pierced Bowman's capsule, as well as about the interlobular arteries and the vessels of the renal cortex generally. This cellular new formation compresses the vessels, and so hinders the proper secretion of urine. The authors therefore regard the presence of this inflammatory product as a very important factor in the etiology of uræmia appearing in the course of inflammatory affections of the kidneys.—*Medical Times and Gazette*, October 28, 1882.

EXTIRPATION OF THE UTERUS PER VAGINAM ON ACCOUNT OF PROLAPSE.—DR. DUVELIUS (*Centralb. f. Gynäkol.*, Aug. 18, 1882) reports the case of a woman operated upon by Dr. A. Martin in Berlin. She was forty-six years of age, and had first menstruated at the age of seventeen. At twenty-two years of age she gave birth to a large child, the labor being normal. Thirteen days after delivery prolapsus began to be noticeable to her, and after a time it became excessive. The cervix was amputated afterward, and anterior kolporrhaphy was performed at one sitting, and posterior kolporrhaphy and perinæorrhaphy at another. The operations were complete failures; the parts projected to an exaggerated degree, and had undergone extensive erosion and ulceration. In this condition she presented herself at Dr. Martin's polyclinic. Another anterior and another posterior kolporrhaphy were determined upon; but, when the patient was anæsthetized, the entirely retroflexed uterus was found to be so completely surrounded by the remains of perimetric inflammation that total extirpation alone seemed practicable. After disinfection of the field of operation, incision was made around the remnant of the *portio vaginalis*, which was followed by free hemorrhage. The uterus was then drawn well downward, and an elastic ligature was placed around it. Douglas's pouch was next opened, and the uterus was detached at that aspect with scissors, knife, and fingers. In a similar manner the separation was made anteriorly. The uterus being now dragged forcibly downward, three ligatures were passed upon either side to secure the vessels, after which it was cut away. The stumps of the ligaments were brought down through the wound, and a series of both deep and superficial sutures was passed, securing the cut edges of the peritoneum and of the vagina. The operation was followed by peritonitis, but the patient eventually recovered. Anterior and posterior kolporrhaphy were subsequently performed, and the patient was believed to be entirely cured.—*New York Medical Journal*, November, 1882.

DISPLACEMENT OF THE KIDNEY AS A CAUSE OF HYDRONEPHROSIS.—In these days, when so many and so varied consequences are imagined by some to result from displacements of the uterus, it is not surprising that a surgeon should have thought it possible for displacement of the kidney to lead to occlusion of the ureter. A case is reported in a recent number of the *Archiv für Gynäkologie*, by Prof. KEHRER, of Heidelberg, in which the theory above indicated seemed to him a possible explanation of the facts. But, unlike many theorists, Dr. Kehrer did not accept the hypothesis as satisfactory without putting it to the proof, and on this account his contribution is of much interest. The patient was aged thirty-two, and had a tumor as big as a man's head, which had been first noticed nearly two years previously. It was tympanitic on percussion—a peculiarity which made diagnosis difficult. The abdomen was opened, the tumor tapped (by which gas was let out and fluid drawn off), and then removed, a small portion, the vascular connections of which were too close to admit of its removal, being left behind. The tumor was found to be an enormously dilated kidney, but no obstruction could be found in the part of the ureter which was removed with it. The patient recovered well. In commenting on the case, Prof. Kehrer points out that large hydronephrosis is only met with when there is long-continued, but not complete, obstruction to the outflow of urine, or when the obstruction is intermittent. Absolute closure of the ureter does not produce a renal tumor of great size. Dr. Kehrer's patient attributed her disease to a strain. It occurred to him, therefore, that the strain might have produced a displacement of the kidney, leading to flexion, and consequent obstruction of the ureter. He proceeded to put this theory to the test in the following manner, on the dead subject. He made an opening in the bladder, so that the outflow of fluid from the ureter could be watched, and then inserted a canula into the pelvis of the kidney. All the other abdominal viscera were left untouched. Water was then allowed to flow into the pelvis of the kidney, and the pressure (twenty to thirty centimetres of water) required to make it flow through the ureter into the bladder was noted. Then the upper end of the kidney was loosened from its capsule, and the organ was pushed into a transverse position. This produced no alteration in the escape of fluid. The kidney was then turned so that its pelvis, with the opening of the ureter, looked directly forwards; but this dislocation produced no appreciable hindrance to the flow through the ureter. Dr. Kehrer therefore dismisses, as being without support from fact, the theory that mechanical change in the position of the kidney can, either by compression or by bending of the ureter, lead to obstruction of the flow of urine through it.—*Med. Times and Gaz.*, October 28, 1882.

Ehrlich's and Gibbes's Methods for Detecting the Bacillus Tuberculosis.—M. W. Vignal suggests the following additions to these methods:

1. It is desirable to keep the staining fluid with the cover-glasses, during a quarter of an hour, at a temperature of 40° Centigrade (104° Fahr.). The coloring matter penetrates more thoroughly, and the bacilli are more deeply and equally colored.

2. It is not advisable to mount the preparations in water, but in a solution of gum, mixed with glycerine, prepared in the following manner. Equal parts of neutral glycerine and filtered solution of gum are mixed together; the gum is of the same thickness as the glycerine, and should be, before mixing, heated in a water-bath with a small quantity of arsenious acid, in order to prevent the development of fungi.

3. Aniline dyes, as Dr. Heron observes, are apt to fade very quickly, but those obtained at Merck's Fabrik, Darmstadt, are free from this disadvantage. All chemicals furnished by this manufacturer invariably give the same results.

4. The tissues from which sections are made should be hardened in alcohol only. Chromic and picric acids, also salts of chromic acid, prevent the staining of the bacillus. This method of staining is based on the theory that the tubercle-bacillus is enclosed in a sheath, which, by alkalies, is softened and penetrated (aniline water, which serves as the vehicle for the coloring matter, is a liquid alkali), but is hardened by contact with acids. Nitric acid combines with the coloring matter of aniline, to form colorless and soluble salts; this acid is thus effectual in removing the color from the other elements of the tissue not required to be stained.

It happens frequently that physicians desire to ascertain whether tubercles contain the tubercle-bacillus, but they have not the time at their command necessary for making sections. In such cases the following method may be adopted: divide the tubercle with a bistoury, then scrape one of the surfaces, spread the scrapings on the cover-glass, and treat them in the same way as the sputum. In preparations thus made, there are very few isolated bacilli. They are present in clusters, and examined by a low microscopic power represent red or blue spots; but when a high power is used, each separate bacillus is distinctly visible.—*British Medical Journal*, October 28, 1882.

Treatment of Goitre by Interstitial Injections of Arsenic.—Dr. Grunmach recommends the interstitial injection of a solution of one part of liquor potassii arsenitis to three of water, in the treatment of goitre. In the case reported the tumor was considerably reduced in size and the interference with respiration caused by pressure on the trachea entirely relieved. The solution was injected in amounts equal to one-half or one-third of a Pravatz syringeful, two or three times each week.—*Berliner klin. Woch.*, No. 32, 1882.

Destructive Ophthalmitis in Children.—Mr. Nettleship, at the meeting of the Ophthalmological Society held October 12th, said that the chief object of the paper was to draw attention to the cases of deep-seated disease which more or less closely simulate glioma of the retina in their clinical features. He believed that there were two principal types of morbid change in this class of cases. 1. Iridochoroiditis, either acute and almost purulent, or chronic: the result of either form being inflammatory opacity in the vitreous, with subsequent detachment of the retina, and backward displacement of the ciliary processes by the shrinking of the inflammatory material. Hemorrhage between choroid and retina might occur. 2. Inflammation and condensation of the vitreous (especially in its outer layers), and in some cases also in its antero-posterior axis, probably the result of a chronic severe retinitis, no detachment of retina occurring. Iritis occurred in nearly all cases of pseudo-glioma, and there was often severe inflammation of the eye in the early period of the case. It was particularly as to the causes of these eye-changes that information was wanted. It was not sufficiently known that the condition called pseudo-glioma (whether following severe inflammation of the eye or not) often came on during, or soon after, some severe illness. Whilst in a considerable number the children were syphilitic, measles, whooping-cough, chickenpox, and perhaps pyæmia and sporadic recoverable meningitis, appeared from the cases (published and unpublished) collected by the author to be the commonest antecedent of these eye-changes. He asked especially for evidence as to the nature of the connection between ocular and constitutional conditions.

Dr. Barlow had seen five cases of this disease; three of them with a suspicion of syphilis, to which, however, he attributed no importance, as he could not see any connection. He inclined to pyæmia as the cause of the changes, and mentioned a case of extensive retinal hemorrhage and detachment of vitreous associated with ulcerative endocarditis. In these cases of pseudo-glioma there was often a history of a convulsive attack, with cerebral symptoms, etc. He thought a number of them were embolic.

Dr. Brailey thought that the cause of these lesions was suppurative inflammation of the vitreous, with consecutive absorption. The tension in these cases was not always diminished; he had found it increased sometimes: diminution of tension could not, therefore, be relied on as a necessary diagnostic sign of non-malignant disease.

Mr. Waren Tay pointed out that double panophthalmitis was not uncommon in epidemic cerebro-spinal meningitis.

Dr. Stephen Mackenzie had no experience of this latter disease, but he had never seen cases of panophthalmitis in cases of sporadic cerebro-spinal meningitis.

Mr. Brudenell Carter referred to a very full report on epidemic cerebro-spinal meningitis by Prof. Hirsch—a translation of which would be found in the *Transactions of the Epidemiological Society*. He thought, if there was any connection between the two diseases, cases would be sure to be found in this report.—*Medical Times and Gazette*, October 21, 1882.

Treatment of Placenta Previa.—M. Hofmeier's conclusions and methods (*Zeit. f. Geb. u. Gynäkol.*) claim our attention on account of the excellence of his results. His material consisted of 46 cases, 35 of which were delivered in one year, thus offering an excellent chance to judge of a method carried out by one man in so many cases. In judging of his method he first excludes from the 46 cases 3 who were so far gone from hemorrhage when he arrived that there was no chance for any treatment. Of the remaining 43, in 19 the location of the placenta was central, in 16 lateral, and in 8 marginal—a very large percentage of *central*.

The usual rule of treatment is to tampon until the cervix is sufficiently dilated. This rule the author opposes. He scarcely ever uses a tampon, and as to the cervix his rule is only to wait till clear symptoms of labor set in, either in uterine contractions or a funnel-shaped dilatation of the cervix. He then proceeds as actively and early as possible. This rule was followed in 37 of the 43 cases, after poor experience in other methods with the rest. In 19 cases the cervix was partially or wholly dilated, in 18 either entirely closed or with only a funnel-shaped dilatation. The earlier the operation the more of necessity is the choice lim-

ited to the combined external and vaginal version with one or two fingers, the Wigand-Braxton-Hicks method. This was done in 30 cases, the foot was brought down in 3 breech cases, three times internal version was performed and once the forceps applied. The combined turning was practised as long as possible, and the hand introduced into the uterus only when absolutely necessary. The feet having been guided to the os, are seized, and by firm traction the buttocks effectually stop the hemorrhage. In cases of central position of the placenta, the author, in spite of all the arguments against it, is in favor of perforating the placenta and bringing the feet through. He did it in five cases, in 3 of which it was necessary on account of haste and in 2 of which the child was already dead. It gives the mother the best chance, and the child's chance is by any method in such a case extremely small. The rest of the delivery, the author expressly states, should be *slowly* accomplished. The condition of the child may modify this rule, but even this must not make us increase the mother's risk. "One must have the courage to let a doubtful child's life be lost in his hands, rather than subject the mother to increased danger. The child is to be delivered *slowly*. Even so, the author's results were not bad as regards the children. Of 37, 17 were already dead; of the 20 still living, 6 died (3 premature, and 3 from perforation of the placenta). Altogether 63 per cent. died and 37 per cent. lived, which is up to the usual standard. The statistics of the mothers, however, are much better. The author considers in them not only the immediate result, but the after-course of the case. In each case ergotin was given subcutaneously during extraction and the uterus was washed out afterwards with a five per cent. carbolic solution.

Of the 37 patients treated by these rules, *one* died. She had been treated for 24 hours by tampon, and the placenta was foul and offensive when the delivery took place, and she died 17 days after from phlegmon and phlebitis of the thigh. Hofmeier believes she would have surely been saved if action had been prompter. This one case, out of 37, gives a mortality rate of 2.7 per cent., far ahead of any published rate, others having been 10 per cent., 16 per cent., and 40 per cent. After-hemorrhages occurred in some cases, but none which could not be controlled with ergotin, iced and hot-water injections. Of the 6 cases treated at an earlier date, and by the *waiting* method, one died: two had a long, severe lying-in; 4 children were dead. Of the whole 46 cases, therefore, 5 died; 10.8 per cent. The author adds two useful hints as to the location of the placenta. In nearly central location the smaller portion is on the side which is more loosened from the cervix lip. In placenta previa lateralis the proportion in favor of the right side is about 11:4.—*Amer. Journ. of Obstet.*, November, 1882.

Ovarian Cyst Suppurating after Parturition: Hyperpyrexia: Ovariotomy: Recovery.—Dr. W. H. Day reports the case of a woman whom he saw in the fourth month of pregnancy with a vaginal tumor probably ovarian in character. She went to full term and was delivered of a living child. When seen one month after delivery she was suckling her child at the time of his visit, but in a few days she was obliged to discontinue it. The abdomen was greatly enlarged and pendulous. The swelling previously mentioned in the vagina had disappeared, and nothing abnormal here could be detected. Over the abdomen, from the umbilicus to the pubes, the percussion-note was dull; above this the note was tympanitic; turning on the right side of the abdomen elicited resonance on the left, and *vice versa*. He considered that there was a large flaccid non-adherent ovarian cyst, containing a thin fluid. The patient was rapidly losing flesh and strength, and looked very ill. Pain and pyrexia were considerable; but, as she had been only confined a month, and there were no symptoms demanding immediate interference, he advised that the operation should be postponed, and the patient carefully watched.

On visiting the patient three weeks later he found her in great pain and unable to move, as peritonitis had been present for some days. He advised that the patient should be kept as quiet as possible, and under the influence of enough opium to subdue pain. He pointed out the necessity of waiting a little to see whether the temperature would fall before having recourse to ovariotomy; tapping, in his opinion, being out of the question. If, however, the patient should become worse, he recommended that the operation should not be delayed, even though the temperature should continue high. For the next few days, the temperature fluctuated between 99° and 102°, and the patient was obviously going from bad to worse.

On July 11, Mr. Spencer Wells, with the assistance of Dr. Emmett, of New York, Dr. Godfrey, Mr. Meredith, and himself, removed a large multilocular ovarian cyst. The cyst was very thin. Extensive adhesions to the abdominal wall and to the omentum were separated, after the cyst had been emptied of a large quantity of turbid flaky fluid, not at all fetid. The pedicle was secured by ligature, which was returned. The left ovary and uterus were healthy. On the third day after the operation, Dr. Godfrey reported that the patient was going on well. Temperature 99°; pulse 94; pain diminishing.

Mr. Spencer Wells removed all the stitches on the ninth day. The wound had healed perfectly by first intention, and the patient went on recovering without interruption. The case is a very striking example of the subsidence of fever, as soon as the cause of the fever had been removed.—*Brit. Med. Journ.*, Oct. 28, 1882.

Treatment of Phagedænic Chancres by Injections of Nitrate of Silver.—Prof. Thiersch (*Centralb. f. Chir.*, No. 27) has been making some experiments with this mode of treatment, and claims that it yields very satisfactory results, though the method should be reserved for the gravest cases, since the injections are so painful that it is necessary to chloroform the patient. A solution of 1 in 1500 is employed, and the injection should be thrown into the thickness of the derm, and not under the skin; the quantity to be injected is 1 c.c., and the injections should surround the phagedænic zone, and be about 1 cm. apart. They should be repeated every week, though occasionally one series of injections will be sufficient to produce a cure. The pain may be allayed by the application of a bladder full of ice.—*Gaz. Méd. de Paris*, Oct. 21, 1882.

Absorption by the Skin of Substances dissolved in Water.—At the meeting of the Académie de Médecine, held October 3, 1882, M. Aubert read a paper with the above title, of which the following are the conclusions:

1. Certain substances dissolved in water may penetrate the skin without their being any external or apparent abrasion of the latter.

2. It appears, however, that there must always be some loss of continuity in the epidermis of the sheaths of the hair bulbs.

3. Absorption is always most active in hairy regions.

4. It is favored by all circumstances, such as friction, which favor injury to the hair follicles.

5. No absorption can take place from medicated baths, no matter how prolonged, unless friction is employed at the same time.—*L'Abeille Méd.*, Oct. 9, 1882.

The Milk of Intemperate Women.—The statement of a correspondent of the *Lancet* that the milk of drunken women contains enough alcohol to burn, raises several very interesting issues. First, as to the presence or absence of alcohol in normal human milk. It is, of course, well known that koumiss is an alcoholic liquor prepared from milk by vinous fermentation of the lactose; the change is a slow one, lactose being of all sugars the least susceptible of fermentation. In the milk of the cow and ass, even when freshly drawn, alcohol was found by Béchamp, the alcohol increasing if the milk was allowed to set. This, of course, suggests the same origin for the alcohol as in the case of koumiss. With regard to human milk, the presence of alcohol, even if found, would suggest a similar explanation, but its presence has never been proved. Still, the wife of the working man is not the first person who has made assertions as to the alcoholic milk of alcoholic mothers. On examination, however, these assertions are seen to be founded not on chemical analysis, but on statements as to the effects of the milk on the infant. In an adult these would, of course, consist of exhilaration, followed by swimming eyes, inarticulate speech, unsteady gait, "dyskinesia" (uterine, no doubt, in female children), and even inability to stand. We may observe many, if not all, of these symptoms in most infants at the breast; and, indeed, in this way the inability to recognize one's own father might be taken as evidence of double vision. Is, then, the whole infant population to be regarded as more or less permanently drunk? Again, evidence may be obtained from the remoter effects of alcohol. We have heard a story of a child who died of cirrhosis of the liver from the prolonged exhibition of steel wine; but we may safely affirm that if even a trace of the alcohol constantly imbibed by a larger portion of nursing mothers were to find its way into their milk, specimens of infantile cirrhosis would be far from rare. On the other hand, there is no doubt that some of the alcohol of alcoholic mothers not unfrequently finds its way into the system of their infants by a more direct route than the milk. Setting aside, therefore, the question of alcoholic human milk as contrary to fact, one question still remains—namely, that of the general effects of alcoholic drinks on the milk of nursing women. To this question no short answer can be given. It may be stated at once, that the diet which ensures the best state of health and nutrition also ensures the best milk, but that no hard-and-fast rule can be laid down on the subject. Overfeeding, as well as underfeeding, will often impair both the quality and quantity of the milk. It is, however, as in so many other questions, highly unscientific to lump all alcoholic drinks together, seeing that in those most generally useful, the alcohol is by no means the principal ingredient. To put gin and mild beer and claret together is to collect strange companions, who have indeed, a common property, but little more. We are, however, within the mark in saying that, special medicinal questions apart, no nursing woman should drink spirits; that the less stimulant she can take (consistently with good health) the better; but it is no less true that in mild malt liquors, and especially in sound porter and stout apparently from the special preparation of the malt, we have a very simple and excellent stimulant to the lacteal secretion in many cases where it flags, and even in some cases where malt alone or other stimulants have failed. Of the impoverishment of the milk of women whose health is impared by drinking there can be no reasonable doubt, and too much can hardly be stated in this respect. We quite agree with the blue ribbon orator so far as this, that if all nursing mothers were teetotallers it would be far better for the totality of British babies. In saying this, however, we must add that some infants would, in our opinion, be the worse: but that, on the principle of "the greatest good for the greatest number," more would be benefited than injured. If only those nursing mothers took stimulants whose health was really improved by them, it would be better still. There are facts which seem to show that alcoholism produces in some women a functional or temporary sterility. On this question, being beside our present subject, and also as not unlikely to serve as an incentive, or at least an excuse, for intemperance, we will not enter. Is it not somewhat of an irony of fate that the teetotal cow and ass should produce alcoholic milk, while the alcoholic human female produces none?—*Lancet*, October 28, 1882.

Treatment of Meningitis in Children.—M. Vovard, at the recent Congress at Rochelle, made a communication on the mode of treating meningitis in children. Three different morbid processes may occasion meningitis in children; the inflammatory process, strumous processes, or tuberculosis. According to him the frequent occurrence of cure in meningitis leads him to conclude that it is not ordinarily of a tubercular but rather of a strumous character.

He recommends the following line of treatment: at the onset of the disease he prescribes iodide of potassium, and after shaving the head, applies croton oil until a pustular eruption is produced, and then maintains free suppuration, which he believes should be continued until the case is no longer in any danger.—*Rev. Scientifique*, October 28, 1882.

The Treatment of Ununited Fractures of the Bones of the Arm.—Mr. Robert Jones reports three cases of ununited fracture, one of the radius, one of the ulna, and one of the surgical neck of the humerus, in which he employed with success the method known to the medical profession as that of percussion. Of this there are two varieties. The one consisting in severely percussing the limb over the seat of fracture at long intervals; the other in its daily, but gentle performance. Whichever plan be adopted elastic bands should also be tied above and below the fracture to induce local congestion and thereby facilitate the reparative process. More especially is this necessary at nighttime when the circulatory system is less active than during the day. The hammering is performed with an instrument covered by an India-rubber cap, so as not to lacerate the soft structures. In its absence, however, anything almost will suffice. In Case 1, the bone being somewhat deep seated, he adopted the method of severe hammering, which he performed once a week. The patient tolerated it very well and complained but little of the pain, although the India-rubber tubes tied around his arm at night made him very restless. He applied no splints, but merely permitted the carriage of his arm slung in hammock-like fashion. This lasted five weeks. After each beating a good deal of swelling and even some contusion marked the occasion. At the end of the fifth week, having noticed a decided thickening of the ends of the bone, he applied splints for four weeks, removing them in time to find union complete. Case 2 is more interesting because more rare. In treating the patient he dispensed with the elastic tubes, and the bone being superficial it was, of course, better to try the gentle mode of percussion than that adopted in Case 1. Accordingly he hammered twice a week and kept the splints firmly applied. In a little over four weeks union was firmly established. In both these cases the treatment gave the patients hardly—if indeed any—more inconvenience than they had already endured. Case 3 differs from the others in being a less confirmed non-union. The patient was ten weeks in splints after

a primary delay of nine days; and it is impossible to say but that another month's continuance would have produced union. He thought it best, however, not to trust to this alternative, and, using his fist for a hammer, he worked away twice a week for nearly two months, with completely satisfactorily results. He mentions that the elastic tubes may be applied immediately after the gentle method, but it is best after the severe mode to wait until the local irritation commences to subside, and thereby prolong it. Should the contusion be very marked, it would, of course, be unwise to apply them at all. As a matter of detail, he adds that the tubing should not always be tied to the same spot, or else ulceration may result. Generally speaking its application at night-time is quite sufficient, and affords the arm very acceptable respite during the day.—*Lancet*, October 28, 1882.

A NEW TREATMENT FOR PURULENT CONJUNCTIVITIS.—The treatment MR. H. L. FERGUSON has been using at the Dublin Infirmary for many months past consists in constant cleansing with an iced 4 per cent. solution of boracic acid, and when the more acute stage is over, touching the conjunctiva with a 10 grain solution of nitrate of silver subsequently neutralized with a solution of salt.

The results with this treatment were on the whole satisfactory, his observations coinciding with those of Mr. Simon Snell, published in the *Ophthalmic Review* for October; but convalescence was slow.

It occurred to him that if the boracic acid were applied to the conjunctiva in a finely powdered state its action would be quicker and more certain, and its application in this way seemed to be free from the objections to iodoform.

Briefly stated, the results of his observations have been: 1. That the application of the finely powdered boracic acid to a discharging conjunctiva checks the discharge completely for a period varying from two to twelve hours, and in the milder cases the first application is sufficient to stop the discharge altogether. 2. When the discharge reappears it is usually less in amount and more watery in character, and a very few applications of the powder stop it entirely. 3. The conjunctiva is then red and succulent but dry, and if touched two or three times with a solution of nitrate of silver it rapidly returns to its normal state.—*Ophthalmic Review*, November, 1882.

NEW TEST FOR THE DETECTION OF ALBUMEN IN URINE.—DR. GEORGE JOHNSON, F.R.S., of London, is now using picric acid for the detection of albumen in the urine. This test was suggested to him by his son, Mr. G. Stillingfleet Johnson, who has long labored at chemical research, and believes that the test is free from fallacy. A saturated solution of picric acid has a specific gravity of 1003, and immediately coagulates any trace of albumen which may be present in the urine to which it is added. The delicacy of the test is strikingly demonstrated when slightly albuminous urine is poured on to the surface of nitric acid and the picric acid solution is added on the surface of the urine. An obvious advantage of the test is that the powdered picric acid may be so conveniently and safely carried in the pocket ready for the immediate and efficient examination of any urine suspected of being albuminous. It is only necessary to throw some of the powder into the suspected urine while it is warm, and to agitate slightly, in order to produce an obvious cloudiness if any albumen be present.—*Boston Medical and Surgical Journal*, November 9, 1882.

TREATMENT OF TYPHOID FEVER.—PROF. KAULICH (*Jahrbuch f. Kinderheilkunde*, xvii.) has obtained excellent results in the treatment of typhoid fever by the employment of the wet pack and quinia; he believes that it is on account of this method of treatment that he has not lost a single child from the disease under his care. In the first hours of the afternoon when the temperature is commencing to rise, he wraps the child in a wet sheet, and while rubbing the child vigorously renews the cold water sufficiently often to prevent the sheet becoming warmed. Sulphate of quinia is then given in doses, varying with the nature of the case, of from fifty centigrammes to two grammes.

This mode of treatment always reduces the temperature, sometimes below normal. M. Kaulich does not believe in delaying too long the return to nourishing food, as he finds that by early feeding the duration of convalescence may be considerably shortened.—*Rev. Scientifique*, October 28, 1882.

ON A PUPILLARY PHENOMENON OBSERVED IN CERTAIN PATHOLOGICAL CONDITIONS IN EARLY CHILDHOOD.—In certain affections of early childhood, with or without convulsions, with or without appreciable lesions of the brain, PROF. PARROT shows that during the period of coma, which is constant, pinching the skin, particularly in the epigastric region, causes a momentary, marked dilatation of the pupil. This effect is most marked in the following lesions of the nervous centre: tubercular meningitis, hemorrhage under the pia mater, chronic hydrocephalus, and in other conditions where there is cerebral compression. On the other hand, in other morbid conditions where coma exists without convulsions, the pupil, which is usually contracted, does not dilate on pinching the skin.

M. Parrot reports twenty-two observations bearing on these two conditions, and gives the following as his practical conclusions therefrom. A child in a comatose condition, whether suffering from convulsions or not, and in which the pupils do not dilate on pinching the skin, is not attacked by meningitis or submeningeal hemorrhage, he is in an advanced condition of asphyxia, and his death is imminent.—*Revue de Médecine*, October 10, 1882.

GRAVES'S DISEASE, COMPLICATED BY OPHTHALMOPLEGIA EXTERNA.—DR. FRANCIS WARNER read a paper on this subject at the meeting of the Royal Medical and Chirurgical Society. The patient was a woman twenty-five years of age, and was the subject of Graves's disease of four years' standing. There was a marked mental excitability, and she was frequently attacked with gastric crises, vomiting, dyspnœa, and palpitation. Both eyes were nearly immobile, a condition not accounted for by the proptosis; this had existed five months before admission into hospital. Limitation of movements was not equal in the two eyes, and was greater in the horizontal than in the vertical directions; double ptosis was marked. There was also bilateral paresis of the seventh and fifth pairs of nerves, and marked tremor of the legs. There appeared to be no evidence of syphilis. Under treatment the goitre subsided, and the general condition greatly improved, but the ophthalmoplegia remains. The unequal amount of paralysis of the two eyes is taken as some evidence of an independent nerve-centre for the movements of either eye, and this is supported by observations in infants in deep sleep and adults in coma, when either eye may be seen to move separately and independently. Again, the greater limitation of movement in the horizontal as compared with the vertical direction is pointed out as probable evidence that separate centres govern these movements respectively.—*Lancet*, October 28, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, NOVEMBER 18, 1882.

INSANE IMPULSE.

ALMOST daily there occurs in some part of this country a startling crime whose motive exists in an insane delusion. In that devotion to liberty which closely approximates to license, we are unwilling to permit any one to be deprived of his freedom who has any possible claim to be regarded as sane. A writ of *habeas corpus* is always attainable by those who have the means to employ acute attorneys and to fee willing experts. The result is that the most dangerous lunatics are constantly at large—for those are most dangerous who to good address, education, and a proper purpose in life, add a delusion which to them seems in the nature of a mission. Such a man soon learns that his view, or his "mission," exposes him to the mistrust of those about him; he becomes very artful in concealing it, but none the less nourishes his purpose in secret.

If such a person can talk intelligently on ordinary topics, especially on affairs of business, and is not induced to talk on his particular delusion, he will appear sound to those who are not aware of this delusion, and physicians unfamiliar with such cases will be readily found to testify strongly in favor of his sanity. Such an example occurred a few days since in New York. A man confined in an asylum for delusions which had led to homicidal attacks, was brought out on a writ of *habeas corpus*. The asylum physicians testified to the existence of delusions of a most dangerous character, but two physicians who appeared to be ignorant of the commonest knowledge of mental disorders, and who are unknown as experts, came forward to swear him sane. One of them, after hearing the testimony of those who had had the lunatic in charge, asked to have the opportunity of re-examining him. The Court gave the necessary permission, and after concluding his investigation the pretended expert was again put on the stand, when he admitted the existence of delusions, but still adhered to his original statement that the prisoner was sane. He appeared to regard him as sane because he could talk intelligently on various topics, and the delusions did not affect his reason and judgment on ordinary matters!

That a physician without any acquaintance with the subject of mental disorders, and simply because he is a physician, should be listened to gravely by a court as an expert, is surely a remarkable phenomenon. That any physician should not know the significance of delusion as an evidence of mental unsoundness, is hardly less astounding. Every lawyer will admit that the existence of a delusion is proof of insanity. The error into which some uninstructed physicians fall, consists in the inability to differentiate between illusion or hallucination, and delusion. A man may have an illusion or hallucination, and yet be able to correct it, but it becomes a delusion when his reason and judgment accept it as real.

A man with a delusion associated with destructive notions, is a most dangerous person, although quite able to appear rational on ordinary subjects. He is the more dangerous because he cannot be confined in due process of law, or if confined can obtain a writ of *habeas corpus* and on the trial of his sanity, procure pseudo-experts by the score to swear him sane. Every day there occur appalling instances of the danger to the public, of giving liberty to such subjects. A few years ago a physician of Milwaukee, was called at night-fall to his front-door by a woman, who rode up in a great hurry in a carriage. As he spoke to inquire her errand, she shot him dead. She was insane, and by mere accident seeing his name in a paper, associated it with some delusion she cherished, although he was an absolute stranger to her, and to her history. Our readers will recall many examples. During the excitement incident to the Guiteau trial, several lunatics moved by deadly purposes, appeared in Washington. We have, heretofore, set forth the well-marked distinction between such lunatics and the men of the criminal class to which Guiteau belonged.

Suicidal purposes are usually entertained by the melancholic. Weighed down by a mountain of grief and supposed wrong, or oppressed by the prospect of a life filled with horrors, they gladly seek a relief from miseries which death alone can

cure, consoling themselves with the idea of the Greek anthology:

"Why fear ye death, the parent of repose
That brings relief to penury and to pain?
His presence once, and only once, he shows,
And none have seen him e'er return again."

In such melancholics the purpose may be only half-formed—barely, indeed, conceived as desirable, and yet at last a sudden impulse sweeps away all counter considerations. The final motive cause may be very trivial indeed, but in the storm of emotions aroused by it all voices are silenced but the cry for the peace of the grave. So small indeed seems the departure from a healthy mental state in such cases that he would be a bold man who could pronounce for seclusion and proper restraint. Furthermore, our notions of allowing the largest liberty to individuals, and the clamor of an irresponsible press with its oftentimes ignorant writers and vituperative criticisms of the conduct of scientific men, constantly oppose action for preserving the safety of society. In respect to this, as to many other evils of our time and civilization, the only hope is in the more general spread of knowledge. The time may come when properly qualified experts will pass on these questions, and press and public will alike accept their decision as final. Meanwhile the number and character of the homicidal and suicidal acts which occur in every community, due to insane impulse, demand a suitable remedy now. It is to be found in a more careful study of these cases, in wiser regulations as to the release of the insane from confinement, and in a more rigid definition of an expert.

DOCTOR ZAY.

FOR centuries a great variety of physicians have figured in fictitious literature. Few writers who attempted to display human life have found it possible to omit all mention of the useful, if not essential, personages who superintended the most important entrances and exits of their heroes or heroines. The medical men have fared on the whole but indifferently well, and, generally through ignorance, have more often been caricatured than truthfully portrayed. Between the biting sarcasm of *Le Malade Imaginaire* and the photographic accuracy of *Middlemarch*, there have been many attempts at depicting the life or character of physicians, most of which, viewed from a professional standpoint, have been lamentable failures. Surely, however, for unlearned assumption of technical knowledge and for innate improbability this latest work of Miss Phelps is entitled to the palm. "Boston women must have an outlet," says one of the *dramatis personæ* of this remarkable production; but let us hope that in the future it may be found in some other direction. We do not believe that even Boston ever produced such a hybrid; such an absolutely inconceivable combination of antagonistic qualities as the female homœopathic physician who figures as the heroine. Young, beautiful, graceful, cultured, sympathetic, her eyes filling with tears at the mention of a lost relative, at the story of a deluded girl, or at the death of a pauper baby, she sets compound dislocations, ligates wounded arteries, hauls drowning men out of mill-dams and resuscitates them, wrests revolvers from maniacs, and fairly revels in an atmosphere of blood, ether, diphtheria, scarlet fever, delirium tremens, and sugar pellets.

If ever love-making was pursued under difficulties it is in this volume. Mr. Waldo Yorke, who began his courtship with what she tells him was a "beautiful dislocation," several severe flesh wounds, and concussion of the brain, kindly has a secondary hemorrhage, and after she has "firmly and fearlessly" arrested that, has only strength enough left to say "Write to my mother. Don't say you are not a man; only say you are not an allopath;" after which he faints—as he deserved to. This, however, is a mere prelude. She attends him through a dangerous illness, consulting by telegraph with a world-renowned homœopathic surgeon of Bangor, whose identity is carefully concealed, and then proceeds to annoy him in various ways.

Whenever he becomes affectionate, her face settles "into an intent and studious form, like a hardening cast," or lights up "with the fervor of the symptomatologist." When she grasps his hand, a procedure not unattended in ordinary love-making with immediate retaliation, he of course feels momentarily encouraged, but without reason; "she lays it down again as if it had been a bottle or a bandage." When she manipulates his ankle and he naturally manifests some excusable warmth, she orders him "one powder dry on the tongue every four hours;" when she takes him out driving, she leaves him to go in and "sew up enthusiastically" a "severed femoral muscle," while he nauseates over the smell of the ether which pervades even the outside atmosphere, and when she rejoins him she views him with a "cool, scientific eye" which, under the circumstances, must have made him tremble for his own femoral muscles. She orders him on different occasions, usually in response to affectionate advances, *cham. 5 m.* and *ars. 2 m.*, and *carbo vegetabilis*, and once "after a silence fraught with significance," says she believes she'll give him "nux." There is no record, however, of her carrying this terrible resolution into effect. She even accuses him, when his eyes burn with ardor and the "values of his face are deepened," of having "a cinchona look;" and when he musters up courage to announce his love, she tells him it is a "nervous sinking-turn," and "without perceptible hesitation"

takes out her medicine-case, the contents of which on this one occasion he repudiates. She finally, of course, consents to leave her practice, which in a small country village averages about fifty visits a day and nets her five thousand dollars per annum, to go as his wife to Boston, with the stipulation that she shall continue to relieve suffering humanity and go out when the night bell rings, or oftener if she chooses.

Justice compels us to admit that Miss Phelps has endowed her with certain characteristics by which we recognize the genuine homœopath. When little Johnny Sanscrit is apparently about to die with diphtheria, she says it is because they did not sooner send off Dr. Adoniram, the "allopath," whom she has previously told her patient she would not trust, and adds bewailingly that "that is too often the way; the patient comes into *our* hands just in time for us to sign the death certificate." Subsequently, however, she is consoled, as Johnny recovers, owing to "a remarkable adaptation of *Lachesis*." She also speaks of herself as the "woman healer," and, indeed, throughout the book, is not at all modest about her professional attainments.

Miss Phelps is a story-teller of no mean ability, and the feminine side of Dr. Zay's character is finely outlined and attractive, but its attempted combination with masculine qualities unusual even in men, and with an offensive display of what the author absurdly imagines to be "unquestionable learning," makes her a ridiculous impossibility—"a faultless monster whom the world ne'er saw."

THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE AND THE ARMY MEDICAL MUSEUM.

A GENERAL regret has been felt by the medical profession that Congress adjourned without making provision for the safe keeping of these important collections. The building in which they are placed is not only insufficient in size and too frail in construction to bear the necessary weight, but it is perilously unsafe, both in itself and its surroundings, in case of fire. It is melancholy to reflect that the largest medical library in the world and the rich accumulations of the museum might disappear utterly in the conflagration of an hour. No physician needs to be told of the value of the library or of its remarkable opulence in medical periodicals, but Congressmen are perhaps not generally aware of the *national* character of this collection and that it is the great mine of knowledge to which the profession of the whole country resort at need. Its destruction would be a loss which no money could replace, and it is earnestly to be hoped that in the coming session an appropriation may be made to provide the fire-proof building asked for by the Surgeon-General.

We have been told that objection has been urged on the ground that the Congressional Library will before long be provided with new quarters, and that the library of the Surgeon-General's office should be consolidated with that collection. Next to its destruction, no worse calamity could befall it than such a change.

Its successful management and the marvellous rapidity with which its stores of learning have been collected are due to the knowledge and zeal of its *medical* administrators. If removed from the control of the Surgeon-General and added to the ponderous accumulations of the Library of Congress, its especial character will disappear, and it will become, like the medical sections of the great public libraries of Europe, of comparative unimportance and of little availability. Every travelled physician knows that in the great cities abroad it is the exclusively medical libraries which attract him. If in London he would not bewilder himself by an excursion to the reading rooms of the British Museum in search of professional lore, but he would straightway proceed to the library of the Royal College of Surgeons, the Royal Medical and Chirurgical Society, or some other purely medical collection.

It is the clear duty as well as interest of the profession to bestir itself in this matter. Let every physician who can, either in person or by letter, convey his views to a senator or congressman, urge upon him the importance of providing a fire-proof building for the library and museum (which ought never to be separated), of keeping the library under the control of the Surgeon-General, and of providing for the completion of its index catalogue, the usefulness of which can hardly be overestimated. Whatever is to be done in the way of acquainting Congress with the opinions and wishes of the medical profession on this matter, should be done within the next three or four weeks, for it is the winter for the short session, and after Congress has met the members will as a rule be too busy to attend to any new business. The House Committee on public buildings and grounds, before which the Surgeon-General's application for a fire-proof building comes, is composed as follows: William S. Shallenberger, Pennsylvania; J. H. Lewis, Illinois; M. E. Cutts, Iowa; M. L. DeMotte, Indiana; J. A. Scranton, Pennsylvania; Nicholas Ford, Missouri; J. Hyatt Smith, New York; Philip Cook, Georgia; J. W. Singleton, Illinois; H. A. Herbert, Alabama; Lewis Beach, New York.

POST-GRADUATE COURSES—CLINICAL OR DIDACTIC.

THE recent development of post-graduate instruction may be due to the expressed and implied needs of young practitioners unfamiliar with the mechanical details of their work, or of older practitioners become rusty, or to the restless ambition of rising

experts, eager to make their way in the most profitable sphere of professional activity. The man who has recently graduated, how high soever his social position may be, how suave his manners, how earnest his purpose, finds that some practical knowledge is necessary to his success; and the rising expert has a keen desire to recommend himself to the favorable consideration of those from whom his future patronage must be largely derived. The former has, after unpleasant, often mortifying experience, learned what he requires to recommend him, effectively, to the public, and the latter for satisfactory reasons of his own is solicitous to instruct him in the much-needed information. Thus we have two powerful motives for the organization of post-graduate schools.

The questions to be determined at the outset are, what is most useful to the physician anxious to qualify himself? In what mode may he best attain to the necessary qualifications? To answer these questions satisfactorily, the kind of practice to be pursued must first be determined. Does the physician desirous of obtaining knowledge, intend to engage in a general or a special practice? If the former, he must have a well-grounded knowledge of the whole field—if the latter, he may confine his efforts to the particular section which he intends to cultivate.

In New York, the post-graduate idea has taken two directions. One school combines lectures with clinical and practical demonstrations; the other deals exclusively with clinical work. In a recent editorial, we decidedly commended the efforts made by our New York *confrères* to give practical direction to the two ideas of post-graduate instruction. But we are of the opinion that much of this method of instruction should be introduced into the regular sub-graduate curriculum, and that without the knowledge that is thereby obtained, a student is not fitted for graduation. The tendency of medical teaching now is to adopt this view and to supplement the didactic lectures with practical and clinical demonstrations in which the students themselves take an active part.

Recognizing the great need of practical eye, ear, and hand training, as a means of fitting the medical man for the work of his profession, Harvard and the two leading medical schools of Philadelphia have regular exercises in laboratory and hospital to secure this to each person. In every department—in clinical medicine, operative surgery, chemistry, materia medica, and physiology—each candidate for the doctorate is taught practically in the best sense of the word. At the Jefferson Medical School and at Harvard there is also an obstetrical laboratory, in which the principal obstetrical and gynæcological operations on the female cadaver are performed in the regular curriculum, in the same way as on the living subject. At the University of Pennsylvania this course is embraced in the spring session, and we are informed that plans are being matured by which each student before graduation shall receive instruction in practical obstetrics at the bedside. The students are thus enabled to carry on investigations, and to perform operations, which in respect to the living subject, they are permitted to witness only. When each student or graduate performs in its entirety, the various operations on the cadaver, he must be much better instructed than he who merely witnesses or assists the surgeon performing them. Indeed, we believe that the most careful surgeons perform on the cadaver any delicate operation, before cutting the living.

In the methods inaugurated for post-graduate instruction, there should be a combination of the clinical with the practical work in laboratory. Hence we fear that a merely clinical school will not accomplish the same good purpose.

New York has certainly taken the initiative in the organization of schools, devoted solely to the instructions of graduates. Philadelphia has for several years provided suitable courses—as we have seen—for the same purpose, in connection with the existing medical colleges, and at the numerous special hospitals. It would also certainly be doing injustice to the Western schools if we failed to recognize the work which they are doing in the same way. Rush, the Medical College of Ohio, the University of Louisville, have provided excellent systems of post-graduate instruction, to which the profession has had access for several years. *Palmam qui meruit, ferat.*

IN connection with the opening of the course of lectures at the Washington Training School for Nurses, on October 23, Dr. D. W. Prentiss, of the faculty of instruction, in his address touched upon three points which are of no little interest.

The want of any means of systematic instruction for male nurses is felt everywhere. We do not know of any place which affords such instruction for men. Their only opportunity to acquire knowledge is in the school of experience in our hospitals. Surely if women have benefited so much by systematic training, men would find even a still greater benefit. A much larger number of men are engaged in nursing than is generally believed, and the services of the best of them are in constant and urgent demand. Yet in the proper sense there is not in any, even of our large cities, a single "trained" male nurse.

Dr. Prentiss also stated that the project of a "Home" which would also serve as a suitable place for a directory for nurses, seemed to be practicable in the near future. He quoted at length from the

circulars of the Philadelphia Directory, to show the need and the usefulness of such an institution. We shall be glad to chronicle its establishment in Washington, where the presence of so large a floating population would make it so especially desirable and useful.

By the way why do not all our Training Schools have formal "commencements?"

We are glad to see that Dr. R. B. Burns of this city, was acquitted in a malpractice suit brought to recover damages in a case of encysted tumor of the breast on which he operated. Not the slightest evidence seems to have been adduced to show that his judgment was not good and his treatment not eminently proper. But none the less does such a suit involve large loss of time and practice and considerable outlay of money and a worriment and annoyance which to most men are more harrowing and wearing than aught else.

REVIEWS.

The Treatment of Diseases by the Hypodermatic Method. By Roberts Bartholow, M.A., M.D., LL.D., Professor of Materia Medica and Therapeutics in Jefferson Medical College. Fourth edition, revised and enlarged. 12mo. pp. 365. Philadelphia: J. B. Lippincott & Co., 1882.

Jason planted the dragon's teeth and an army represented their fructification. The history of planting the conception of the hypodermatic syringe forms the introduction to the writer's thoughts on hypodermatic medication, and lo! what a progeny of chapters follow: over three hundred good-sized pages, in which more than twenty medicinal substances receive notice. Completeness and succinctness characterize the book. Morphia and atropia receive an exhaustive account of their physiological and therapeutical action. The antagonistic effects of the latter drug with physostigma, pilocarpine, muscaria, bromal hydrate, and aconite, will give an idea of the wide range of subjects covered. The thoroughness of each article bears witness to the learning and research of the author. It is an epitome of the subject and much valuable information can be gained by its perusal. But as few things in this world can be said to be complete, we notice that although the hypodermatic use of pilocarpine is discussed in relation to its efficacy to abort malaria, no allusion is made to the use of chloroform, an agent which has been employed for the same purpose and reported on by the late Dr. Berens, of this city. The size of the volume has been increased by the introduction into some of the chapters of material more appropriate in a general treatise on therapeutics. Considerable space has been given to the toxicology of special drugs, as, for instance, morphia and atropia, and the directions for the use of strychnia in spinal affections do not apply only to the hypodermatic use of the drug.

Clinical Lectures on the Diseases of the Nervous System. By Thomas Buzzard, M.D. Lond., etc. 8vo. pp. 466. Philadelphia: P. Blakiston, Son & Co., 1882.

This book ought to have been entitled, lectures on some diseases of the nervous system. It is occupied for the most part with tabes dorsalis (posterior spinal sclerosis) and associated disorders. The first two lectures are on tendon reflex, and give a full account of the objective phenomena which are held to be due to a reflex action. The elements of the reflex are these: the reception of an impression by the peripheral nerves and its transmission to the cord; the development of a motor impulse and its reference outwardly to the muscles concerned in the action. In tabes dorsalis, this tendon reflex fails, because of a break in the circuit at the roots of the sensory nerves—in the posterior columns.

Lectures III. and IV. are occupied with infantile paralysis, and a good account of "the reactions of degeneration" is given—a topic well worthy of study by those who think electricity of little use to the physician.

The greater part being devoted to various phases of tabes dorsalis, this malady is fully discussed. He gives a particularly full account of the joint changes, and the gastro-intestinal derangements—"gastric crisis"—which belong to this strange disease.

Several forms of paraplegia, including the cervical and syphilitic, are discussed. Every topic is handled with care and even with minuteness, but the author makes the impression that he accomplished his task with ease because of an exact acquaintance with the subjects discussed. The work is easy reading, for, although many of the topics are difficult, everything is clearly stated, since the author himself has formed a definite conception. The mechanical execution of the work is excellent.

Cerebral Hyperæmia—Does it Exist? A Consideration of Some Views of Dr. W. A. Hammond. By C. F. Buckley, B.A., M.D., formerly Superintendent of Haydock Lodge Asylum, England. Pp. 129. New York: G. P. Putnam's Sons, 1882.

This brochure, as its title indicates, is a controversial work, intended solely to disparage Dr. Hammond's views. These views may, or may not, be correct, and having been published to the world are legitimate objects of a proper professional criticism. But is the criticism just? What is the motive? There is abundant evidence that the critic has transcended the proper boundaries of professional criticism, and has not correctly stated the views which he professed to be combating. He is therefore handicapped at the outset with a load which renders his best efforts impotent. What his motive may be does not appear. He seems to be an Englishman who has adopted this, as the readiest means for making himself known to the medical profession of this country. Quite apart from the merits and demerits of Dr. Hammond, or of his critic, there is the important clinical fact—*does cerebral hyperæmia exist?* Dr. Hammond says it does, and many of the ablest clinicians of our time say it does exist. Dr. Buckley denies it. After a resurvey of the question, it is our deliberate conviction that Dr. Buckley is wrong. Dr. Hammond may not be right in the views which he has promulgated, but it seems to us Dr. Buckley is clearly wrong. There are some unquestionable clinical facts and physiological studies which seem to prove that the amount of blood in the brain varies from time to time; that it is now present in excessive quantity—that it is now deficient in amount. That the intra-cranial blood pressure may not vary with the conditions affecting it, is certainly very extraordinary doctrine. There is a mechanism—the cerebro-spinal fluid moving through the foramen magnum—by which the blood-pressure is regulated. When the vessels are full the perivascular lymph spaces are encroached on,

the cerebro-spinal fluid is displaced. The converse is equally true: when the cerebro-spinal fluid is excessive, the blood is displaced. Such is the mechanism of the "wet brain," as described by pathologists—a wet brain, because it is an anæmic brain.

The best authorities recognize cerebral hyperæmia as a distinct morbid state. For example—Jaccoud, gives an excellent account of the several forms in which this state manifests itself. Trousseau devotes a lecture to it; Flint and Bartholow, also, recognize it as a morbid state; only Dr. Buckley questions its existence. We should be inclined rather to regard Dr. Buckley as mistaken, than that those who have made the subject a study have failed to recognize its true relations.

SOCIETY PROCEEDINGS.

MEDICO-CHIRURGICAL SOCIETY OF MONTREAL.

Stated Meeting, October 20, 1882.

(Specially reported for THE MEDICAL NEWS.)

R. A. KENNEDY, M.D., PRESIDENT, IN THE CHAIR.

AFTER routine business DR. OSLER exhibited the following specimens:

AMPHISTOMA CONICUM,

a fluke which is not uncommon in the paunch of ruminants. The specimen showed forty or fifty adherent to the mucous membrane by means of the powerful caudal sucking disks. They appear to be especially abundant in the cattle in Pictou Co., Nova Scotia, as nearly all the animals examined in connection with the so-called "Pictou cattle disease" presented numerous examples.

FATTY DIARRHŒA.

A small bottle full of oily material passed by a woman aged 33, a patient of Dr. Woolverton, of Hamilton. The woman had been ailing all summer with slight gastro-intestinal trouble, and latterly had been passing a quantity of fat with the stools, as much as a pint in twenty-four hours. It was yellowish in color, and of the consistency of melted butter, and was sometimes passed unmixed with the feces, usually with a gush of wind. She had a dislike to fat and only took what was contained in ordinary diet.

DR. WOOLVERTON thought that more was passed than could be contained in the food. In a subsequent letter he stated that after lasting ten days the fat has entirely disappeared and the woman felt much better.

OBLITERATED SUPERIOR VENA CAVA,

from a patient of Dr. Wilkins, who had been in hospital about three months with symptoms of venous obstruction in the chest—lividity, swelling of face and upper extremities, urgent dyspnœa and constant dropsy of the pleura, necessitating frequent tappings. The mode of onset and the origin of the trouble were obscure. At the post-mortem the vein was found to be completely obliterated and converted into a firm fibrous cord about the thickness of the thumb; firm organized thrombi extended into the internal jugulars. Section of the vein an inch from the auricle showed a dense grayish-white peripheral portion and a central grayish-red, more porous substance. No other lesion was found. Dr. Osler remarked that this was the third specimen of obliteration of the great venous trunks, which had been presented to the Society within the past three years; the others being obliteration of the inferior vena cava (*Journal of Anatomy and Physiology*, 1879), and obliteration of the portal vein (Ibid., 1882).

ABSCESS OF LUNG IN PNEUMONIA.

DR. MOLSON narrated the case. An intemperate woman, aged 35, was admitted to the General Hospital on the fourth day of an attack of severe pneumonia. Resolution did not take place, and on the tenth day she began to spit up quantities of very offensive, purulent matter. The temperature, which had kept up to about 104°, fell to 99°, and death followed on the eleventh day. There was extensive pneumonia of the right lung, and the specimen exhibited showed a large, ragged abscess cavity in the lateral region of the lower lobe. There was also recent pericarditis, and a thin sheeting of lymph lined the inner surface of the dura mater of the right side.

TAPPING THE GALL-BLADDER.

DR. OSLER showed eighteen ounces of thick bile, obtained by aspiration from the gall-bladder of a patient with the following history: A farmer, aged 58, of average health until the spring, when he began to have pains in the back and shoulders—did not feel "right in himself." In June he noticed that the urine was dark-colored, and that his face was becoming yellow. There has been a heavy dull pain over the liver, but never paroxysmal attacks or any vomiting. The jaundice has deepened, and he is now intensely icteric. The stools have been clay-colored, and the itchiness of the skin has been intolerable. He has lost flesh, but the appetite has been uniformly good. The liver was found greatly enlarged, smooth, painless, and projecting from beneath the right border was a rounded tumor, evidently a distended gall-bladder. This was aspirated and emptied. No gall-stones could be felt. The jaundice has not been relieved, and the nature of the obstruction has not yet been determined.

PHLEGMONOUS CYSTITIS.

DR. BELL exhibited a bladder from a man who had fallen into the hold of a vessel and broken the third and fourth dorsal vertebræ. He lived for ten days, and had symptoms of intense cystitis. The bladder was swollen and the mucous membrane transformed into a dirty, yellowish, sloughy layer. The inflammation had extended up the ureters to the kidneys; there were sloughs on the mucous membrane of the pelves, and scattered foci of suppuration through the substance.

SENILE ATROPHY OF BONES.

DR. F. J. SHEPHERD exhibited the femurs of a woman between 80 and 90 years of age, the subject of general fragilitas ossium or senile atrophy of the bones. The left femur had the characteristic deformity of osteo-arthritis, the neck being shortened and the head enlarged, and the acetabulum also enlarged. Just above the condyles in this bone was an old united fracture. In the right femur there was an ununited intra-capsular fracture. Dr. Shepherd remarked that all the bones in this case presented an unusual degree of fragility; the astragalus could be broken by pressure of the finger and thumb; the skull cap was only of parchment thickness.

CANCER OF THE ŒSOPHAGUS; PERFORATION OF THE LUNG.

DR. GEORGE ROSS showed the specimen and gave the following history: J. M., aged 54, was admitted to hospital October 10, with cough, pain in the epigastric region, and weakness. In May he had had pain beneath the sternum and in June there were symptoms of obstruction in the gullet; solids would be regurgitated, and he has lived on soft foods ever since. About three weeks ago he began to cough and noticed a very foul odor with the expectoration. When admitted he was anæmic and emaciated. At the base of right

lung there were bubbling râles; expectoration seropurulent and fetid. Liver enlarged, smooth, not particularly tender. A large sized bougie was readily passed into the stomach, and the patient swallowed dry bread without difficulty. In spite of the negative signs the case was considered to be one of cancer of the œsophagus, with secondary affection of the lung and possibly of the liver. At the autopsy the gullet presented an enormous cancerous mass occupying the lower half of the tube, terminating about an inch from the cardia and involving the entire circumference with the exception of a narrow groove-like portion on the posterior wall. The edges of the mass were swollen and infiltrated, the base deeply excavated, and at one margin it had perforated the right lung near its root and was in communication with a series of sloughing abscesses. There were numerous secondary masses in the liver.

DR. MILLS commented on the ready passage of the bougie in this case, and thought it might perhaps be explained by a turn of the instrument. He thought it would have been a good case for the auscultation of the œsophagus.

DR. ROSS thought ausculation would probably have failed, inasmuch as there was no obstruction but œsophagoscopy might have been serviceable. The bougie had doubtless passed along the groove at the back of the gullet, which had acted as a sort of director; indeed when the specimen was on the table and unopened, Dr. Osler had passed a bougie at his request, and each time it slipped down without any obstruction.

DR. MILLS explained the mechanism of Dr. Morell Mackenzie's œsophagoscopy apparatus; he did not agree with Dr. Ross as to the value of auscultation in such a case, for, although no obstruction was present, yet the walls of the tube were so diseased, that they could not act muscularly, and thus in swallowing the sounds would be sufficiently delayed to be appreciated by the stethoscope.

DR. OSLER thought that ausculation might have afforded valuable evidence in this case, and remarked that he had seen an instance in which it was of considerable diagnostic importance.

LACERATION OF THE KIDNEY.

DR. RODDICK reported the case and exhibited the specimen. A healthy woman, aged 60, had fallen down a long flight of stairs, and was picked up insensible. There was no wound, but on recovering consciousness she complained of great pain in the right loin; vomiting began, and in spite of all treatment, continued to the end. The bowels became tympanitic and refused to act. Pure blood was passed from the bladder during the first twenty-four hours; subsequently, the urine was mixed with blood, and on the fourth day it was nearly clear. Rupture of the kidney was diagnosed, and ileus was suspected on account of the obstruction of the bowels and their great distention, though no tumor could be felt. Rectal injections were employed without any benefit. At the autopsy a large clot of blood was found surrounding the right kidney, which presented a laceration on the border, extending into the pelvis of the organ. The kidneys were firm and slightly granular. The bowels were distended but not obstructed; it was thought that perhaps the large blood clot might have pressed upon the ascending colon and produced the obstruction.

HÆMATEMESIS IN CHRONIC ENLARGEMENT OF THE SPLEEN.

DR. OSLER read a short paper calling attention to some points in connection with this subject. He alluded in the first place to the frequency with which hemorrhages are associated with all forms of chronic splenic tumors, more especially those accompanying leucocythemia. A depraved blood condition would seem to be an important factor, as they are also common in profound anæmia without splenic enlargement. Epistaxis is the most frequent, and next hemorrhage from the bowels, but hæmoptysis, hæmatemesis, and hæmaturia are occasionally met with. Of 150 cases of leucocythemia, collected by Gowers, hemorrhages occurred in eighty, and in eight of these from the stomach. The point to which he wished to call attention, was the possible occurrence in some instances of severe, perhaps fatal hemorrhage, even before the constitutional symptoms were marked, or even before symptoms sufficiently pronounced had aroused the suspicion of patient or physician.

The following cases were given in illustration:

Case I. Early Hæmatemesis in Splenic Anæmia.—J. H., aged 36, admitted to hospital September 3, 1879, with anæmia. Has been healthy and temperate. Served with the army in India where he had intermittent fever. In January, 1879, when in apparent good health, he had an attack of vomiting of blood. Within a week the bleeding recurred twice, and each time he lost a considerable amount and was greatly reduced. In July he had a single large hemorrhage from the stomach, and afterwards severe diarrhœa. Up to this time he had had no symptoms pointing to enlargement of the spleen but he now began to feel a sense of weight and distention in the abdomen, which soon became evidently swollen. He entered hospital with anæmia, enlarged spleen, ascites, and œdema of the ankles. He had no hemorrhage while under observation and during the month in hospital the dropsy disappeared, and his blood condition materially improved. He was taken to the country by his relatives and died suddenly of a profuse hæmatemesis.

Case II. Early Vomiting of Blood in Splenic Anæmia.—A. B., aged 11, a well-nourished, stout little girl, came under observation on August 13. The mother gave a history of good health in the child up to two years ago, when, during a slight indisposition, with some abdominal pain, she had a severe attack of vomiting of blood, lasting over twelve hours. She recovered and seemed to regain her usual health, though pale and subject to headaches. In July, a brother died, and the excitement brought on another attack, which lasted thirty-six hours, and in which she lost a couple of quarts of blood. She recovered rapidly, and at the time of observation appeared well nourished, but pale and a little puffy under the eyelids. She complained of a fulness in the abdomen, shortness of breath on walking fast, and loss of appetite. Examination revealed enlarged spleen, extending about three inches below the costal border; abdominal veins not distended; no ascites; blood-corpuscles about fifty per hæmic unit.

Case III. Fatal Hæmatemesis in Leucocythemia.—A. B., aged thirteen, under the care of Dr. R. P. Howard, a plump, well-nourished boy, had been at school and playing as usual. On the 13th of April had a severe attack of vomiting of blood, and shortly after, a large bloody stool. For four days there was repeated vomiting, and he brought up in all about four pints of blood. Death followed on the fourth day. Enlargement of the spleen was detected and a leukæmic state of the blood. The boy had not been under medical care prior to the sudden onset of the bleeding, but four years before had passed blood with the stools. At the autopsy the spleen was found enlarged, and weighed 480 grammes. There were no erosions or ulcerations in the stomach.

Case IV. Sudden and fatal Hæmatemesis in unsuspected Leucocythemia.—A young American lady on a visit to the city was attacked with violent hemorrhage

from the stomach which proved fatal within twelve hours. She had been in apparently good health, her father was a physician and had not any idea that she was even ailing when she left home. She was under Dr. Howard's care. At the autopsy the spleen was found enlarged and firm and the blood was leukæmic. There were erosions or ulcerations in the mucous membrane of the stomach.

In reply to a question from Dr. Buller, DR. OSLER remarked that the bleeding was doubtless due in many instances to an impoverished blood-state with an enfeebled condition of the capillary walls; but in others it might be from mechanical causes. Three-fourths of the blood from the stomach is discharged into the splenic veins, and in states of engorgement of these a stasis or interference in the gastric circulation might be brought about, sufficiently intense to necessitate relief by rupture of a vessel or a diapedesis of blood into the stomach.

DR. ROSS referred to the occurrence of early hemorrhage from the stomach in early stages of cirrhosis of the liver.

MARION COUNTY, INDIANA, MEDICAL SOCIETY.

Stated Meeting, November 1, 1882.

(Specially Reported for THE MEDICAL NEWS.)

DR. GEORGE J. COOK, formerly Professor of Anatomy in the Kentucky School of Medicine, but now of Indianapolis, read an interesting paper on

THE ANAL SPHINCTERS AND THEIR AGENCY IN THE CAUSATION OF CONSTIPATION.

He said that Dr. O'Bierne, of Dublin, was the first to demonstrate by numerous explorations of the human rectum, in 1833, that it is not a receptacle in which feces accumulate during the intervals between the periods of defecation. Before that time it was never doubted that the feces passed freely along the colon and were not stopped until they reached the rectal pouch. Dr. O'Bierne examined persons in a few minutes after defecation, and others at the moment when they felt a moderate inclination to go to stool, and found that the rectum was perfectly empty and contracted at both these periods. The anatomy of the rectum shows an ill-construction for the purpose of a reservoir, and differs greatly from the large intestine. The rectum contains two strong layers of muscular fibres, longitudinal and circular. The three longitudinal layers of the colon pass down over the rectum, two anterior and one posterior. Besides the "sphincter of O'Bierne," at the upper part of the rectum and the external and internal sphincters below, we have the "sphincter ani," composed of a semi-circular band of fibres about three inches from the anus, and a posterior one about an inch higher than the anterior, and above the rectal pouch. The lower fibres of the posterior band run obliquely downward and form the upper border of the anterior band. These have been clearly demonstrated by Dr. Chadwick, of Boston. The upper part of the rectum when empty being firmly contracted, and these circular bands being stronger than other parts of the rectal walls, strong and prominent projections are formed in the inside of the gut, which can be easily felt in the healthy rectum as two semi-circular folds or constrictions. It is this constriction which is so often diagnosed as stricture, when by its firm contraction it offers obstruction to the free passage of the rectal bougie, which lodges against the superior bundle of constricting fibres, and if the bougie is pressed firmly onward, it will lodge against the sacrum below the promontory. Lynn reports a case where three hundred hours were spent by a reputable surgeon in dilating a stricture of the upper part of the rectum which the *post-mortem* proved did not exist, but that the end of the instrument had lodged in this fold against the sacrum.

The valvular arrangement claimed to have been discovered by Mr. Houston, of Dublin, in 1830, has been clearly shown not to exist by Busch, Chadwick, and others. Gray, Wilson, Heath, Ellis, Quain, and Harrison speak of the valves of the rectum, and give Houston as their authority, which gives the student a very wrong idea of the anatomy and physiological action of the rectum. Cruveilhier does not speak of any such valves. The rectum, especially the lower portion, receives a more abundant blood-supply than any other part of the large intestine. The nerve-supply to the rectum comes from two sources—from the hypogastric plexus of the sympathetic, and from the fourth anterior sacral nerve, being the only part of the intestinal canal which receives branches direct from the spinal nerves, which accounts for its greater sensibility and irritability than any other portion of the intestines. The external sphincter receives a greater nerve-supply than any other muscle in the body, being supplied by branches of the internal pudic, the fourth sacral, and the posterior sacral nerves, which also supply the integument over it, and the vessels and pelvic organs and external organs of generation. The spinal nerves supplying all the pelvic viscera, the structures of the perineum, and external organs of generation, are given off from the same point in the spinal cord, which accounts for the numerous reflex phenomena encountered about the pelvic organs—the spasmodic contraction of the sphincter ani attendant upon an inflamed prostate or bladder or irritation of the urethra, by inflammation or the introduction of a bougie, or chronic inflammation of the lower part of the uterus.

The proper receptacle for feces is the sigmoid flexure of the colon, which hangs down in the pelvis like a bag with the ends turned up, which position specially adapts it for a receptacle for the feces, where they are arrested until the period for their final discharge, which is accomplished by the sigmoid flexure rising out of the pelvic cavity into the iliac fossa as it becomes filled. This, together with the contraction of the colon, obliterates the acute turn in the gut between the colon and rectum, giving free passage to the contents, which are forced onward by the contraction above and relaxation below of the muscular fibres of the gut. When the mass reaches the perineum, the abdominal muscles come into play and assist in the final repulsion. Just as the last part of the *mass* is ready to be expelled, the levator ani contracts and raises the perineum, which seems to be necessary to the discharge of the last part of the feces. The longitudinal fibres assist in drawing the gut up over the mass.

The external sphincter is a purely voluntary muscle and contracts by both reflex action and direct volition. The rectum will not tolerate the presence of feces in it for any great length of time without education. When the expulsion of feces is voluntarily resisted for any length of time, a reversed or anti-peristaltic action takes place, and the feces are returned to the sigmoid flexure. By a repetition of this from time to time, the rectum is gradually educated to tolerate what is really irritating to it, and it is only educated rectums that are found full of fecal matter between the periods of defecation. This education begins by persons daily refusing to respond to the calls of nature. The rectal walls, from over-distention and exertion, lose their strength and irritability and are finally reduced to a state of atony. At the same time, the sphincter is becoming hypertrophied and increases in strength. The constant presence of a fecal mass in the rectum and its pressure on the terminal branches of the internal pudic nerves

at the upper border of the internal sphincter produces increased irritability of the muscle and a much stronger automatic contraction, which increases with the irritation of the muscle until the muscle will cease to respond perfectly to the will, when it is the desire to thoroughly relax it, and the once voluntary obstruction becomes an obstruction beyond the power of the will to entirely overcome. The internal sphincters soon get to acting the same way. Contraction takes place by reflex action caused by irritation from the fecal mass and will not relax until forced to by the advancing feces, which requires the aid of the abdominal muscles, and then an atonied rectum is never entirely emptied.

The same irritability of the sphincter is often produced by chronic diseases of the surrounding organs which are intimately connected with the external sphincter through the nervous system. Whatever may be the cause of this contraction of the sphincter, when it is continued long enough to produce atony of the rectal walls, chronic or obstinate constipation is the result. The sphincter muscle in these cases is always found firmly contracted and increased in size and irritability, making it difficult to introduce the finger into the rectum. Both rectum and sigmoid flexure are filled with feces, and the rectal walls have little strength to assist in expulsion. By the combined efforts of the rectum, colon, and abdominal muscles, the sphincter is dilated and the mass expelled, except the upper portion, which is left in the rectum until the next effort.

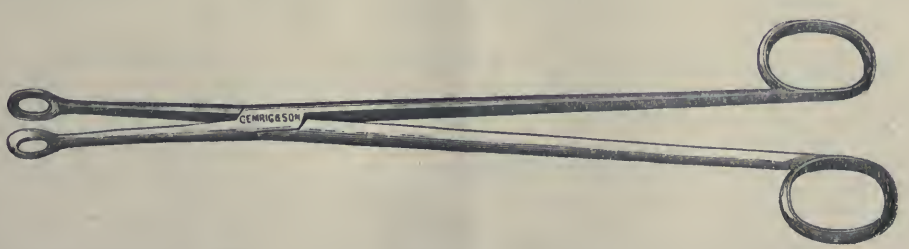
The watery portion left is absorbed and a dry mass left for the next discharge. The various rectal diseases produce irritability of the muscle with the above consequences. Obstruction by the external sphincter is the prime cause of constipation in the majority of cases. Atony of the rectal walls, which is always present in these cases, is usually the result of obstruction, and not the prime cause of the constipation.

NEW INVENTIONS.

A NEW OVUM FORCEPS.

BY A. E. SPALDING, M.D.,
OF LU VERNE, MINN.

EVERY physician has no doubt been occasionally perplexed in treating cases of miscarriage which occur from the fourth week to the third month. The tampon, which is undoubtedly used more than any other method of treatment, is very useful, but in several cases I have seen alarming hemorrhage occur with the vagina packed completely with pledgets of cotton. In such cases the ovum should be removed as soon as possible and when it can be reached with the finger, I think it better to remove it in that way than to use any form of instrument, but frequently we feel the ovum partially detached, rolling around within the uterus, and still we are unable to withdraw it.



I have found the instrument which I had made for me by J. H. Gemrig & Son, of Philadelphia, as shown by the accompanying cut, to answer the purpose of detaching and removing the ovum admirably. It is made the size of the common uterine dressing forceps, with the exception of the jaw, which is fenestrated, the edges are smooth and rounded so there is no danger of injuring the uterus, and its size is such that it is easy of introduction.

CORRESPONDENCE.

A LETTER FROM GENERAL WASHINGTON TO DR. JAMES CRAIK.

WE have received the following interesting and hitherto unpublished letter from General Washington to his intimate friend and physician, Dr. James Craik, from Dr. Weir Mitchell, to whom it was sent by Mr. George Bancroft, the historian, with the accompanying note:

"Here, my dear Doctor, you see the relation between physician and friend in the last century. The letter is enough to wring the heart for the sufferings of the best of mortals. Ever yours,

"GEO. BANCROFT."

"MOUNT VERNON, 4 August, 1788.

"DEAR SIR: With this letter you will receive the horse I promised you, and which I now beg your acceptance of. He is not in such good order as I could wish, but as good as my means would place him.

"I also send you thirty pounds cash for one year's allowance for the schooling of your son, G. W. I wish it was in my power to send the like sum for the other year which is now about or near due, and that could discharge your amount for attendance and ministrens to the sick of my family, but it really is not, for with much truth I can say, I never felt the want of money so sensibly since I was a boy of fifteen years old, as I have done for the last twelve months and probably shall do for twelve months to come.

"Sincerely and affectionately,

"I am, yours, etc.,

"GEO. WASHINGTON."

CAFFEINE IN HEADACHE.

To the Editor of THE MEDICAL NEWS.

SIR: In December, 1878, I was called to treat a lady suffering from a very severe headache. For some years she had had emphysema of the lungs and, resulting from this, frequent attacks of dyspnœa.

When I saw her she complained some of difficult breathing and was purple about the face, but the headache was agonizing. I tried several remedies without avail and remembering to have seen caffeine recommended in a general way for headache, I resolved to give it a trial. Accordingly at my next visit two grains of this drug was directed to be given every half hour until the patient was relieved. After the first dose she became easier and soon the headache ceased entirely.

Some time after this I was [illegible] a lady for an attack of pericarditis, who had long had asthma. Upon visiting her one day I found her complaining of violent headache, and I noticed a dark hue about the

face; calling to mind my former experience, she was at once put upon two grain doses of caffeine every half hour. It acted like a charm and promptly afforded relief.

Another lady had pneumonia: she was the patient of a brother practitioner and I was called to treat her in his absence; found her comfortable in every way with the exception of severe headache. I noticed a dusky tinge of the face and gave two grains of caffeine every half hour. After the second dose she became easy.

Since the above experience I prescribe caffeine in headache, if there is a dusky hue about the face, with as much confidence of relieving my patient as I feel in the use of quinia for ague. This drug has long been used for headache, but, so far as I am aware, no particular indication has heretofore been given for its use. My usual prescription is 16 grains of caffeine to one ounce of simple elixir, and dose, teaspoonful—frequently repeated if necessary.

I am, sir, yours,

Chas. B. Johnson.

Champaign, Ill., November 5, 1882.

CINCINNATI.

(*From our Special Correspondent.*)

Clinical Teaching of Obstetrics.—Your readers in this city were much surprised by the excitement of the Philadelphia Hospital authorities concerning Dr. Warder's recent delivery of a woman during his lecture in the hospital amphitheatre. Dr. Warder did only what should be demanded of every teacher of the obstetric art in these times. We are gratified to note—just what we expected—the full spirit of this sentiment in the editorial which appeared in The Medical News a fortnight ago. In our city clinical teaching is regarded fully as imperative in this as in any other department of practice. When Prof. Reamy, several years ago, first brought an obstetrical case before his class in the amphitheatre of the Medical College of Ohio, there was some little unfavorable criticism even on the part of members of the profession, and severe comments in a few of the secular papers; but the benefit to the student and the public was so patent that for years he has delivered from three to six cases annually before his class without objection from any quarter; it is now regarded as an established and necessary feature of obstetric teaching here. No difficulty whatever is encountered in getting subjects for these clinics. Poor women voluntarily enter the obstetric wards especially established for this purpose, with the express understanding that they are to be taken before the class at the time of delivery. That any serious objection to a feature of such necessity should be raised in Philadelphia, which has so long been justly regarded as a centre of medical education, is a matter of astonishment to us in the West.

Remarkable Case of Melanosis.—One of the most remarkable cases of melanosis on record was recently reported by Dr. Wm. H. Falls, of this city. The skin of the entire body gradually changed its color until the man, once of light complexion, became as black as a negro. Impaired vision, resulting in complete blindness, was the initial symptom, being due to the deposition of the melanotic masses in the choroid. The urine, black as ink, was highly albuminous. The subcutaneous nodules, widely distributed over the entire body, varied from the size of a millet seed to that of a cherry. With the exception of occasional convulsions the patient's intellect remained clear to the end. Death resulted from paralysis following one of these convulsions. Melanotic masses were found in various parts of the brain and all the other viscera. These proved, on microscopic examination, to be melano-sarcomata. A detailed clinical history of this most interesting case, which lasted ten months, will, with illustrative lithographic engravings, and full *post-mortem* and microscopic accounts, be published in an early issue of the *Lancet and Clinic*, of this city.

BROOKLYN.

(*From our Special Correspondent.*)

Scarlet Fever at Flushing.—At Flushing, Long Island, scarlet fever has prevailed to an unusual extent, and the authorities have found it necessary to close one of the town schools.

BREWSTERS, PUTNAM COUNTY, NEW YORK.

(*From Our Special Correspondent.*)

At the Quarterly Meeting of the Putnam County (N. Y.) Medical Society, held October 24, the following resolution was adopted:

Resolved, That this Society does not approve the Code of Ethics adopted by the State Society, at Albany, in February, 1882.

CANADA.

(*From our Special Correspondent.*)

The Number of Doctors in Canada.—From the *Ontario Medical Register* just issued we learn that there are on the list of qualified practitioners 1919 names. 175 members practice outside the Province, and the addresses of 86 are unknown; so that there are about 1700 medical men. The census of 1881 gave 1,913,460 inhabitants, making about one medical man to every 1125 inhabitants.

Progress of the Yellow Fever at Pensacola.—The telegraphic reports received by the National Board of Health for the six days ending November 12th, are as follows:

Dates.	Cases.	Deaths.
November 7,	7	1
" 8,	3	3
" 9,	9	2
" 10,	3	0
" 11,	4	2
" 12,	11	1
Total,	37	9
Previously reported,	2243	185
Total,	2280	194

Dr. Hargis, President of the Pensacola Board of Health, expresses his views on public sanitation in a letter to Dr. White, of the Marine-Hospital Service, published, November 10, in the *Times-Democrat*, of New Orleans. "Furthermore," he says, "I take the occasion to deny, as has been asserted, that the National Board of Health has, to my knowledge, in a single instance attempted to trench upon the rights or prerogatives of any State or local board of health. From the time the National Board of Health was organized, and up to very recently, it was apprehended without just grounds, or even any reasonable grounds at all, that a new centralizing power should usurp the duties devolving upon State and local organizations, but even one year's service, during which the scope of its duties were carefully defined by able statesmen, showed conclusively that all such apprehensions were but the creations of a morbid fancy.

"The National Board of Health has its own special field of operation clearly and accurately limited, and within those limits it alone could act and did perform. It could not, even if it would, have assumed functions, which belong to and were performed by State and local authorities except by co-operating with them, but it was the fault of State and local boards that lack of harmony and concord of action ensued, as I predicted.

"The interests of commerce, and of the whole world, are bound up in the great question which I, for one, am glad to see intrusted for action and deliberation to the National Board of Health. That our colleagues in that Board will not betray their trust, nor act rashly, is universally acknowledged. I am in favor of an extension and not limitation of their powers, and under the guidance of Hon. Isham G. Harris, State authority can never be forgotten."

CHOLERA IN JAPAN.—The cholera which has been ravaging certain ports of Japan, and especially the ports of Yokohama and Osaka since April last, is now officially announced as having disappeared from the country. Advices from the United States Legation Tokio, Japan, state, that on the 26th of September the enforcement of the quarantine laws had been suspended at Kobe and other ports in respect of vessels arriving from Yokohama; and that on the 6th of October the enforcement of the said regulations had been suspended in respect of vessels arriving from Osaka, the cholera having disappeared from the said port. By virtue of these orders of suspension, quarantine laws are not now enforced at any port in Japan. Reports from Yokohama to the National Board of Health, dated October 16th, state that, since September 29th, no new cases of cholera have been reported as occurring in the city and vicinity, and that clean bills of health are now being issued to vessels leaving the port. Up to that date the total figures reported were 3,619 cures and 2,328 deaths, giving a mortality of 64.22 per cent.

THE ORGANIZATION OF A BOARD OF HEALTH AT PATERSON, N. J.—After a long delay a Board of Health has been established at Paterson, N. J., under the laws of the State. This step has been urged by the citizens ever since the late outbreak of smallpox, and the indications are that it has been taken none too soon, as under the old condition of things, there was a lack of authority for the officials to enforce the abatement of nuisances promptly, and to take proper measures for the compulsory movement of smallpox patients to quarantine.

The Board of Aldermen, at its meeting on last Monday night, passed the ordinance establishing a Board of Health, and the Mayor immediately appointed as members Dr. John Quin, Dr. E. J. Marsh, Henry L. Butler, and James Beggs. The appointments were confirmed. The other members are, ex-officio City Physician, C. F. W. Myers; Health Inspector, W. K. Newton; and George Boyd, the Register of Vital Statistics. The Medical members of the Board are all regular physicians. Dr. Quin is one of the Aldermen. Dr. Marsh is President of the Passaic County Medical Society. Mr. Butler was recently one of the Inspectors of the New Jersey State Prison, and is a member of the commission appointed by Governor Ludlow to examine into the question of water supply for the cities of New Jersey. Mr. Beggs is an engineer. It is thought that the members of the Board are of such character as will secure the enforcement of all necessary sanitary measures.

The situation is still considered grave. There have been six new cases of smallpox reported during the first three days of this week, and three of these were in localities where the disease had not previously existed. One of them was in a house on Arch Street, on which a sign was placed to warn people of the presence of the infection. Some unknown persons removed this sign several times after it had been replaced by the authorities, so City Physician Myers had a notice inserted in the local papers, warning the public. Two deaths were reported on Tuesday.

HARVARD UNIVERSITY.—The Corporation of Harvard University have passed a vote formally according to the Medical Faculty, that no matters relating to medical education should be acted on in the future until the Faculty should have had a full hearing upon the subject at issue.

The text of this vote has just been made public among the official records of the Corporation in the *University Bulletin* for October, and reads as follows:

Voted, that a standing committee of two members of this Board be appointed with whom the Medical Faculty may confer on any matters relating to medical education in the University.

The President appointed Messrs. Parkman and Agassiz as this committee.

Voted, that the President and Fellows deem it inexpedient to legislate in matters relating to medical education in the University without first offering to the Medical Faculty an opportunity of expressing its views.—*Boston Medical and Surgical Journal*, November 9, 1882.

DR. FLINT'S LECTURES BEFORE THE PHILADELPHIA COUNTY MEDICAL SOCIETY.—DR. AUSTIN FLINT, of New York, will deliver in the hall of the College of Physicians a course of three lectures on "The Physical Exploration of the Lungs by Auscultation and Percussion," before the Philadelphia County Medical Society, on the evenings of Saturday, November 25th, December 16th, and January 13th.

The subjects of the lectures are:

Lecture I. The True Mode of Study and its Requirements as Regards Auscultation and Percussion. The Signs obtained by Percussion.

Lecture II. Auscultation; and the Respiratory Murmur, with its Abnormal Modifications.

Lecture III. The Râles and the Vocal Signs.

The profession are invited to attend the lectures.

DR. HAMILTON'S BILL FOR PROFESSIONAL SERVICES TO PRESIDENT GARFIELD.—Dr. Frank H. Hamilton, of New York, in submitting to the Board of Audit his bill, amounting to $25,000, for services rendered to the late President James A. Garfield, wrote to Judge Lawrence, under date of October 18, as follows:

"I received you note of the 19th ult., calling my attention to the fact that the Board of Audit is awaiting the presentation of any claim against the estate of the late President. Availing myself of your suggestion that I may make to the board any further communication which I may deem proper, I will say that in presentation of a claim which I know cannot be paid out of the sum, $35,000, placed at your disposal by Congress, my intention is only to indicate to you what I would regard as the minimum compensation for similar service in case of a private person who was pecuniarily responsible, and who would not be embarrassed by payment of such sum. I will further say that while I do not make for myself any relative claim, I must protest against the presentation, on the part of one of the physicians in attendance, of a relative claim to the effect that he is entitled 'to receive double the fee of any other physician in attendance,' which claim was laid before the House committee, and may have been laid before your board."

The letter was accompanied by a specific statement

of the nature of the services rendered at the conclusion of which Dr. Hamilton said: "These circumstantial statements I make with great reluctance; but they seem to be rendered necessary by the fact that there are intimations to the contrary contained in the report of the House committee, and obtained apparently from sources which the committee considered reliable. Moreover, Congress has chosen to place the payment of the medical attendants upon a purely business basis, and your board has therefore properly instructed the claimants to 'describe fully the services rendered.' The sole item which I have to present to your board, as the basis of my claim, is my long attendance upon the late President as a consulting surgeon, with its accompanying responsibilities, which God forbid I shall ever again be called upon to bear."

COMMENCEMENT OF DARTMOUTH MEDICAL COLLEGE.—The graduating exercises of the Dartmouth Medical College were held on Tuesday evening, November 14th. After prayer by President Bartlett, an address was delivered by Dr. D. W. Jones, of Portsmouth. A thesis was read by J. F. Larocque, and the Valedictory was delivered by Hilary J. Moore. After an address by President Bartlett, and the bestowal of prizes, the Hippocratic oath was administereed by Prof. C. H. Frost, the degree of M.D. was conferred upon the graduates, of whom there were twenty-one. The first prize for the best examination in all branches was awarded to John Nottage, of Nashua, N. H., and the second, for the best examination in the practice of medicine, to E. N. Mullins, of North Londonderry, New Hampshire.

THE NATIONAL ACADEMY OF SCIENCES held its annual meeting this week in New York. Prof. O. C. Marsh, of Yale, Vice-President, presided, and Dr. G. F. Barker, of the University of Pennsylvania, acted as secretary. A number of scientific papers were read, but none of them had any special bearing on medicine.

LECTURES AT THE NEW YORK ORTHOPÆDIC DISPENSARY AND HOSPITAL.—The Trustees of the New York Orthopædic Dispensary and Hospital announce that Dr. Newton M. Shaffer will give a course of clinical lectures, on orthopædic surgery, at the Institution, on Thursday afternoons, at half-past four o'clock, from November 16, 1882, to February 15, 1883, inclusive. The course will be free to the medical profession and students.

Subjects: Ankle-joint Diseases, Knee-joint Diseases, Hip-joint Diseases, Pott's Disease, Club Foot, Knock-knee and Bow-legs, and Lateral Curvature.

THE BROOKLYN EYE AND EAR HOSPITAL on Thursday evening gave a reception, so as to afford an opportunity to the friends of the Institution, and the subscribers to its recent building fund, to inspect the new alterations and additions. Through the kindness and liberality of some of the friends of the Institution a simple collation was served in the dining-room.

SIR THOMAS WATSON, BART.—The whole profession will learn with deep concern that the health of this revered physician has during the last few days been a source of anxiety to his family and friends. He had for some weeks past been staying with his son at Reigate. On Sunday last, although now in his ninety-first year, he was in his usual good health and attended the morning service. On attempting to rise from his chair after lunch he suddenly inclined towards the left side, and would have fallen on the floor if he had not been supported by his son. He afterwards took a short walk in the garden, but there was an evident weakness of the left leg, and this continued to such a degree that he is now unable to walk without assistance. There is no appreciable loss of power in the arm, but the tongue when protruded deviates slightly to the left. There has been no drowsiness, and he is in complete possession of his mental faculties. His kind neighbor, Dr. Walters, of Reigate, is in daily attendance, and he has been visited by his old pupil and friend Dr. George Johnson, to whom he calmly remarked, "This is the beginning of the end." His medical attendants are agreed that there is probably some arterial obstruction by thrombosis in the neighborhood of the right corpus straitum. —*Lancet*, October 28, 1882.

PERSONAL.—A telegram to the *N. Y. Tribune* says that the health of Ex-Surgeon General Barnes continues to be so feeble as to excite the gravest apprehensions of his friends. Dr. Woodward, another of President Garfield's physicians, has been steadily sinking for several months past, and no hopes of his recovery are now entertained.

PROF. NOTHNAGEL was enthusiastically received by the students and professors on the occasion of his first official appearance, on October 16, as a member of the Vienna medical faculty. His introductory lecture was an eloquent tribute to the memory of his predecessor, the late Prof. Duchek.

MR. J. N. LANGLEY, of Trinity College, Cambridge, has been appointed teacher of physiology.

MR. A. SEDGWICK, the late Prof. Balfour's assistant, has been appointed to the lectureship held by Mr. Balfour before his election to the professorship.

THE BALFOUR MEMORIAL.—A large and influential meeting of gentlemen connected with the two Universities has been held at Cambridge, in connection with the proposed memorial to the late Prof. Balfour. The Vice-Chancellor presided. It was agreed, on the motion of Prof. Huxley, that the memorial should take the form of a fund, to be called the Balfour Fund, for the promotion of research in biology, especially animal morphology. At the close of the meeting it was stated that the Balfour family would give £3,000, and Dr. Michael Foster £1,000. Dr. John Willis Clark has been appointed treasurer to the fund.—*British Medical Journal*, October 28, 1882.

THE NEXT INTERNATIONAL CONGRESS OF HYGIENE will meet at the Hague, in January, 1884.

THE HEALTH OF THE EMPEROR OF GERMANY.—It is reported that the Emperor of Germany is suffering from some nephritic disease.

BANQUET TO THE MEDICAL OFFICERS OF THE EGYPTIAN EXPEDITION.—It is proposed in London, at an early date, to give a banquet of welcome to the medical officers of the British army and navy who served in the Egyptian expedition. Sir William Jenner, Bart, K.C.B., President of the Royal College of Physicians, will take the Chair.

THE PROCEEDINGS OF THE ROYAL MEDICAL AND CHIRURGICAL SOCIETY.—The Council of this Society has decided on making some innovations in the conduct of the proceedings of the Society. Hereafter printed abstracts of the papers to be read are to be supplied before each meeting, in sufficient time to allow members two or three days for the consideration of the subject; and, on the evening of the meeting, a sufficient number are to be laid on the table for the use of the members present. Hitherto, only a written abstract of each paper has been placed in the Society's room for inspection before the meeting. Authors are

also to be allowed to read their own papers if they prefer to do so, instead of having them read by the secretaries.

Prof. Virchow.—At the last meeting of the Berlin Medical Society, Prof. Virchow was installed anew in the president's chair. Virchow's bust, presented by his assistants, has just been erected in the hall of the Berlin Pathological Institute.

Excision of the Pylorus.—On Oct. 17th, at St. Thomas's Hospital, Mr. Sydney Jones removed the pylorus for malignant disease. The patient, aged fifty-seven, was under the care of Dr. Bristowe. A large growth completely surrounding the pylorus, together with some affected glands, was removed. The operation was a prolonged one, and was carried out with antiseptic precautions. The patient was much emaciated before the operation, and unfortunately did not rally from the shock, dying about six hours afterwards. We hope shortly afterwards to publish the particulars of the operation and morbid appearances.—*Lancet*, October 28, 1882.

Nephro-lithotomy.—On the 21st of October, at the Queen's Hospital, Birmingham, Mr. Bennett May performed this operation on a man 34 years of age. The stone, weighing 473 grains, was extracted entire through an incision in the kidney, which was healthy. The case, which promises to be an interesting contribution to the operative treatment of renal calculus, will be published when complete. At the present time the patient's condition is excellent in every respect.—*British Medical Journal*, October 28, 1882.

A New Vegetable Styptic.—A recent number of the *Neue Freie Presse* states that during the French expedition to Mexico a plant was discovered, called by the natives by a name which may be rendered as "Fowlwort" (Tradescantia erecta, Jacq.), which has the property, when chewed or crushed, of stopping any hemorrhage. A specimen planted in 1867 by the discoverer, in his garden at Versailles, has not only flourished, but flowered and fruited, without having its peculiar properties as yet appreciably diminished. Although no exotic, or remarkable for particular beauty of bloom, it, nevertheless, deserves a wider extension on account of its valuable properties, especially as its acclimatization may be regarded as having been fully established. Its action exceeds that of all styptics as yet known, as, for example, perchloride of iron, and it can, moreover, be very cheaply procured.—*Lancet*, October 28, 1882.

Preservation of Dead Bodies for Identification.—Every corpse that is taken to the Paris Morgue is now quickly converted into a block, almost as hard as stone. This result is obtained by Carré's chemical refrigerator, which is capable of reducing the temperature of the gruesome "conservatory," where each body is laid out on something closely resembling a camp bedstead in stone, to 15° below zero Centigrade. At the back of this *salle* is a row of stove-like compartments in which the corpses are boxed up and frozen hard before being exposed to public view. As an illustration of the intense cold thus artificially secured, a Paris journalist, in describing a recent visit to the Morgue, says that in opening one of the compartments the attendant took the precaution to wear a glove lest "his hand should be burnt by contact with the cold iron." The corpse, which was taken out of its receptacle, had been there nine hours. During the experiments which preceded the adoption of the new system, corpses in this frozen state were actually thrown about, but although they made *un fracas terrible*, they were "not in the least damaged."—*Med. Times and Gazette*, October 21, 1882.

Disinfection of Hospitals.—M. Miguel has recently undertaken a series of experiments with reference to the destruction of the numerous micro-organisms held in suspension in hospital wards. It having been ascertained that many bacterial germs resist, for a period of two hours, dry air warmed up to 145° or 150° Centigrade (293° to 302° Fahr.), his investigations were made on chemical agents specially. After having satisfied himself that atmospheres loaded to saturation with the vapors of chloroform, carbolic acid, ammonia, sulphurous acid, sulphide of carbon, hydrocyanic acid, and nitrous ether, are powerless to destroy all the germs contained in floating dust, even after twenty days' action, he directed his attention to a class of corrosive substances, which destroyed these so-called germs as certainly as a long-maintained temperature of 200° Cent. (392° Fahr.). Thus, an atmosphere saturated with iodine-vapor at the ordinary temperature destroyed every schizophytic germ at the end of ten days. Bromine, diffused in the air, produced the same results at the end of two days; hydrochloric acid gas, of an equal volume, acted at the end of the same time with similar efficacy; the vapors of nitrous acid and moist chlorine gas had the same effect; but the damage produced by these extremely corrosive agents on wood, linen, and metals rendered the destruction of bacteria by these processes a very costly proceeding. It must be remembered that bacteria, and not mould, is in question; for the spores of the commonest forms of mould resist the powers of those agents that can destroy bacteria.—*British Medical Journal*, October 28, 1882.

Public Health in Connecticut.—From the report for September of the Connecticut State Board of Health we learn that the month of September can hardly be classed among the healthy months of the year when the mortality tables are consulted, together with the usual average of at least five cases of sickness for each death. These taken together indicate the category to which the month must be referred. The large proportion of deaths from zymotic diseases, those rightly classed as preventable included, is a marked feature. The protracted heated term gives also a large addition in the cities from cholera infantum, using the term comprehensively; convulsive disorders, and infantile debility are also prominent, showing the depressing effects of unsanitary surroundings upon infant life. Hartford stands prominent as an illustration of the prominence of these diseases, as they cause nearly fifty per cent. of the mortality of the month. Ten deaths are reported from typhoid fever, a large number even after those brought into the city to the hospital are deducted.

The principal diseases of the month have been diarrhœal and dysenteric diseases, typhoid fever and malarial diseases. There has been some diphtheria, whooping-cough—scarlet fever—rather more than the usual number of diseases of the nervous system, and a larger number of cases of erysipelas; cerebro-spinal meningitis is reported in one or two instances, two fatal cases from Bridgeport, one from Avon. A large number of towns report more or less typhoid fever, comprising nearly every part of the State, indicating quite a general prevalence. In Portland it could almost have been called epidemic there were so many cases.

This return of typhoid fever to prominence, and its steady increase in frequency for the last three years, is apparently a part of an extensive and comprehensive movement, as the epidemic of malaria was ushered

in by a decrease, and in places almost if not quite a total disappearance of typhoid. This return of typhoid fever to its former importance and relative frequency is an intimation of the decrease and disappearance of malaria. The tendency towards typhoid fever commenced several years ago, and has steadily grown stronger each year as shown by the increased prevalence, tendency to unusual frequency and severity, and the increase each year of deaths from this cause. As the decrease in the frequency of typhoid preceded the malarial wave, so its increase precedes the entire disappearance of malaria, but gives us some ground for hope that such a disappearance will take place. This disappearance of epidemics of malarial fever, on a large scale, has often been followed by an unusual prevalence of typhoid fever or an extensive epidemic. The epidemics of malarial fever of 1807 and 1824, which are stated to have extended over all Europe, were followed by typhoid fever. Of course it is as yet but an inference that the present malarial influence which has extended continuously over the greater part of this State into Massachusetts and Rhode Island is subsiding and leaving its first points of invasion. But there is much to encourage such an idea. It is quite a prevalent impression that there has commenced a steady decrease in the general frequency of malaria in the west and southwestern parts of the State. However that may be, the return of typhoid fever, the tendency towards a continued type shown by malarial fevers, the large percentage of typho-malarial fever, forming 86 per cent. of the mortality from malarial diseases last year, or 222 out of 357 deaths, are obvious facts.

Whether or not malaria will become endemic in any part of the State is a question of interest that time only can determine. The idea has been advanced that the southwestern part of this state is a border-land where the epidemic influence from the southwestern regions (especially Westchester County where malaria is endemic), finds a resting-place whence, if reinforced repeatedly, or strong enough originally, it invades other parts of the State. The same tendency before noted to greater severity in regions where it has existed for some time continues, while few cases of acute intermittent occur. Thus congestive chills are reported in several instances, one fatal case in Hartford, one in Meriden. A singular fact often illustrated is the tendency to acute intermittent shown by new comers, even if they come from a malarious region, and have had ague previously. What at first looked like a fresh recurrence of acute intermittent was found on investigation to be mainly confined to the new families that had recently moved from New Jersey.

The conclusion to be drawn from the sanitary history of the month is the need of closer attention to the sources of disease. If every city would employ sanitary inspectors under the direction and control of the boards of health, as does New Haven, the results would be as apparent as they are there. If a nuisance must exist until it becomes unbearable, which is generally the case, before any one complains, much harm is caused that is avoided under the other plan. Persons, then, that if left to themselves, pollute their own premises and adjacent unoccupied spaces, with decaying organic matter, or have other unsanitary tendencies, would be checked and kept in order, if they knew that some one would look after them at any time, when least expected, and take them to task for their shortcomings.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending Nov. 4, 1882, indicate that tonsillitis has considerably increased, that scarlet fever and typho-malarial fever have increased, and that intermittent fever and diarrhœa have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending Nov. 4, and since, at 25 places, scarlet fever at 19 places, measles at 2 places, and smallpox at 2 places, as follows: at Niles, and at Grand Rapids (one new case) Nov. 4.

OBITUARY RECORD.—Died at Lattingtown, L. I., October 30, in the 86th year of his age, JAMES C. TOWNSEND, M.D.

Dr. Townsend studied medicine with his uncle, the late Dr. Thomas F. Cock, of New York, and graduated in 1820, from the College of Physicians and Surgeons. He settled in his native place, Lattingtown, and for more than half a century practised there and in the vicinity. About a year or two since, the growing infirmities of age induced him to abandon his professional career, which had been active and extensive during a period of years allotted to but few of his compeers. He was one of the founders of the Queen's County Medical Society, and an active member thereof until the close of his life. Possessed of a robust physique, an active and well-cultured mind, and a public-spirited disposition, he was long known as a wise counsellor not only in matters professional, but in the furtherance of interests affecting the common weal. His estate is said to be valued at $125,000, the fruit, in no small measure, of his long and successful practice.

—— Died at Burlington, Vt., on Tuesday, November 14, aged 65 years, SAMUEL WHITE THAYER, M.D., Emeritus Professor of Anatomy in the Medical Department of the University of Vermont.

Dr. Thayer was born in Braintree, Vermont, on the 21st of May, 1817, of New England parents, whose ancestors emigrated to this country from Wales in the early part of the seventeenth century. He received his medical education at the Vermont Medical College, Woodstock, and graduated in 1838. He settled in Woodstock, but in 1840 he removed to Northfield, in the same State, and in 1853 he established himself at Burlington. In 1854 he was made Professor of the Theory and Practice of Medicine in the Medical Department of the University of Vermont, and was subsequently transferred to the Chair of Anatomy. During the war of the rebellion he was made Surgeon-General of Vermont. Dr. Thayer's professional laurels were won chiefly in the domain of surgery, and he is said to have twice successfully amputated at the shoulder, and removed the entire scapula and half the clavicle. His widow and one son survive him.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 6 TO NOVEMBER 13, 1882.

AINSWORTH, F. C., *Assistant Surgeon.*—Granted leave of absence for one month, with permission to apply for extension of one month.—*S. O. 120, Department of Texas, November* 1, 1882.

AINSWORTH, F. C., *Assistant Surgeon.*—The leave of absence granted November 1, 1882, is extended one month.—*S. O. 121, Military Division of the Missouri, November* 9, 1882.

BREWSTER, WM. B., *Assistant Surgeon.*—On being relieved by acting Assistant Surgeon Potter, will proceed to Fort Bridger, Wyoming, reporting to the commanding officer thereof for duty.—*S. O. 116, Department of the Platte, November* 4, 1882.

MCELDERRY, HENRY., *Assistant Surgeon.*—Upon arrival of Assistant Surgeon Brewster at Fort Bridger, Wyoming, to be relieved and ordered to Fort Robinson, Neb., to report to the commanding officer thereof for duty.—*S. O. 116, Department of the Platte, November* 4, 1882.

BRECHEMIN, LOUIS, *First Lieutenant and Assistant Surgeon.*—Leave of absence for five months granted.—*S. O. 259, par 2, A. G. O. November* 6, 1882.

VOL. XLI. SATURDAY, NOVEMBER 25, 1882. NO. 22.

ORIGINAL LECTURES.

TREMOR.

A Clinical Lecture delivered at the Pacific Medical College, San Francisco.

BY J. O. HIRSCHFELDER, M.D.,
PROFESSOR OF CLINICAL MEDICINE.

(Specially reported for THE MEDICAL NEWS.)

WE have before us, Gentlemen, a patient who presents a peculiar tremor for our consideration. Besides a purulent gingivitis, nothing abnormal is to be found. There is no other disturbance of motility and no alteration of sensibility. In a word we have to do with gingivitis and tremor. If we examine more closely into the character of this tremor we find it involving all four extremities. We see the parts quiet under ordinary circumstances, but a tremulous movement as soon as an effort is made. When the patient stands with his eyes closed he does not totter, but his legs tremble in the same manner as did his hands when he extended them. Tendon reflex is normal. Our patient informs us that for a year and a half he has labored over the furnace of a quicksilver mine, and that three months ago the tremor, and with it salivation, set in. Since this time both have increased in severity. We have before us a case of mercurial intoxication.

If we inquire into the diseased conditions attended with tremor, we will find the latter present in the following pathological states: paralysis agitans, disseminated sclerosis, alcoholism, syphilis, chronic intoxications, and neurasthenia.

Tremor may be produced either by alternate contraction and relaxation of antagonistic muscles, or it may be brought about by irregular innervation of the muscles involved. Under normal circumstances the contraction of a muscle is not a simple single contraction. It is not due to a single impulse from the nerve centre. Waves of nerve force pass during the entire duration of the contraction from that centre to the muscle. It takes a certain measurable time for a muscle to pass from a state of contraction to that of relaxation. If the nervous impulses pass from the centre to the muscle so frequently that the relaxation following the contraction caused by the previous impulse has had no time to pass off before the succeeding impulse arrives, an apparently continuous contraction of the muscle is the result. If, however, the waves of nerve impulse do not pass to the muscle in such rapidity, if a relaxation of the muscle has already been produced before the succeeding wave arrives, no continuous contraction occurs but a tremor.

In the animal body we may for the sake of simplicity consider that the nerve force travels from the centre in the brain to the ganglia of the cord, and thence through the motor nerves to the muscle. For the purpose of illustration we may consider the nervous power to be a fluid, the nervous fibres tubes conveying this fluid, and the ganglionic cell cups in a state of unstable equilibrium so arranged that when this equilibrium is overcome the fluid passes through the tube forming the motor fibres to the muscle. I have said the ganglionic cells are in a state of unstable equilibrium, for you know that a certain amount of nerve force is necessary to produce their activity. If less than this amount be communicated to them, nothing results. Now, we imagine this cup in a state of equilibrium which may be more or less stable; that is to say, the ganglionic cell is more or less irritable. Under ordinary circumstances, the nervous fluid passes from the brain through the nervous tubes and flows into the ganglionic cups. As soon as sufficient has accumulated to overcome the equilibrium, a discharge of the fluid into the motor nerve-tube occurs, and a flow of nervous fluid to the muscle, producing a contraction thereof. While this passage from the ganglionic cell to the muscle is going on, a flow from the brain to the ganglionic cell occurs, which again overcomes its equilibrium, and so before the muscle has had time to pass from its state of contraction to relaxation another wave has come. And so a continuous contraction results.

Now, under pathological conditions, the state of equilibration of the ganglionic cups may be altered. The cup may be balanced nearer its centre of gravity, and so require a larger quantity of nerve fluid to produce a discharge (the cell is less irritable), or it may be balanced further from its centre of gravity (the cell be more irritable). If we imagine the irritability of our cell to be diminished, or, to translate into the terms of our illustration, the equilibration of our ganglionic cups to be made more stable, then it will require the accumulation of a greater amount of nervous fluid to cause its discharge, and if all the other conditions remain the same it must take longer for the cup to be filled to its point of discharge, and therefore the number of discharges in a given time be diminished. Hence, the waves would pass so unfrequently to the muscle that it had time to pass to a condition of relaxation before each succeeding wave arrives, and hence a tremor would result.

Or the nerve-tube through which the nervous fluid passes may be narrowed, so that in a given time a less quantity of fluid can pass to the ganglionic cup, so that likewise the number of discharges in a given time would become reduced. In medical parlance a diminished conductivity of the nervous fibre might cause tremor. Or the muscle itself might be less irritable, so that it would require a greater quantity of nerve force to produce a contraction, and again tremor would result.

It is probable that one other factor is of great importance in the production of tremor, namely, the quantity of nervous fluid which passes from the brain in a given time. It is probable that, in the condition of neurasthenia, that is, nerve exhaustion, less nervous force is generated than under normal conditions. This is however, as yet, a dark, unexplored field. To sum up that which has preceded. we may state tremor may be caused:

1. By exhaustion of nervous centres in the brain.
2. By diminished conductivity of nerve fibres.
3. By diminished irritability of motor ganglionic cells.
4. By diminished muscular irritability. It may be likewise produced by the alternate contraction of antagonistic muscles which occurs in chill. We would add then:
5. Contraction and relaxation of antagonistic muscles.

We are, as yet, too little familiar with the *molecular* changes produced in the nervous system by various pathological lesions to state definitively to which of these five causes the tremor in the individual case be

due, but through this classification a direction may be given to further investigations.

Where we have a tremor independent of voluntary effort, as in paralysis agitans, we must assume that there is a continuous flow of nerve force to the muscle, but not sufficiently rapid to cause continuous contraction, as is the case in tetanus; but, instead, a tremor. We have as yet been baffled in our search for the cause of paralysis agitans, and so the attempt at explanation of the origin of its symptoms is futile.

ORIGINAL ARTICLES.

SPONGE GRAFTING.

By W. L. ESTES, M.D.,
MEDICAL SUPERINTENDENT OF ST LUKE'S HOSPITAL, SOUTH BETHLEHEM, PA.

Since the publication of Hamilton's paper with the above title in the November number of the *Edinburgh Medical Journal* for 1881—proving not only the innocuousness of properly prepared sponge on living tissue, in common with other properly treated animal substances, and also demonstrating its usefulness in pathological conditions—surgeons on both continents have experimented with varying success according to his method. Having had my attention turned to this line of surgical therapeutics even before seeing his article on the subject, I was stimulated by his success as well as that of one or two followers, whose results have since appeared, to a systematic trial of the method I had already determined upon. I do not accept Dr. Hamilton's theory of granulation, viz., that "the bloodvessels have a constant tendency to be forced outwards into loops, but in the normal condition are restrained by compression from the fasciæ and skin;" when, however, by a solution of continuity of these tissues the vessels are relieved of their pressure, "the action of the heart forces them outward into loops, and they are covered by cells produced by multiplication of connective tissue corpuscles from over-nutrition." While retaining the common idea that the capillary loops are new formations from the underlying bloodvessel, his theory of support afforded by the sponge to these capillaries, and the largely additional facility furnished by the protection of the sponge meshes for the generation of fibro-cellular tissue from the mucoid covering of the blood-tracts, accorded entirely with my former reasoning. Much encouraged, therefore, I set about experimenting with *small bits of sponge as grafts on ulcers*.

I selected fine surgical sponges, had them thoroughly beaten, in order to remove the sand and loose calcareous particles, carefully washed in cold water, and then soaked in dilute hydrochloric acid (officinal acidum muriaticum dilutum, about proper strength) for forty-eight hours; after this, carefully washed in several relays of cold water, in order to remove the acid entirely; and lastly, put into a well-stoppered jar filled with five per cent. solution of carbolic acid. They must remain in the five per cent. solution for at least a week, and are then ready for use. In grafting, the ulcer is carefully disinfected with a two per cent. solution of carbolic acid, taking care not to rupture any capillary, for I have found that hemorrhage into the bits of sponge seems to prevent their absorption. Hands, instruments, and everything likely to come near the ulcer, must also be carefully disinfected. As many pieces of sponge as are desired are now snipped off and allowed to fall into a basin of two per cent. solution of carbolic acid. With a pair of forceps these are successively removed and carefully laid among the granulations; when they are all applied the ulcer is covered with a piece of "protective," and a full Lister dressing applied. The size of the pieces used is about one-tenth of an inch—about the size of an ordinary skin graft. The dressings are generally removed on the third day, reapplied, and the subsequent dressings made, as the case requires. Strict antiseptic precautions should be kept up for a week at least. On the third day I have always found (with one exception which will be mentioned further on) that all the grafts are firmly adherent. If examined carefully at this time with the unaided eye, it will be noticed that each graft is surrounded by a faint white zone, which by a magnifying glass is resolved into radiating bands of lymph inclosing minute bloodvessels which run into the sponge. If now a piece be removed, it will be found pretty firmly fixed, and its removal will be followed by quite an appreciable hemorrhage. Examined microscopically at this time, the interstices of the graft are seen to be pierced in every direction by a network of capillaries, and a number of large nucleated cells permeate its whole substance. After seven days the bits of sponge are seen as small white points in the granulations, entirely covered by lymph and firmly embedded in the granulations. At this time it is difficult to remove them. If a piece be removed, the circumference will be seen to be very ragged, the piece itself seeming to be diminished in size. Examined microscopically the capillaries and large nucleated cells fill the sponge everywhere and the proper sponge substance is beginning to disintegrate. From this time they are steadily absorbed. In fourteen days they are usually not to be seen, or only indistinctly under the granulations. While it is the rule for all the grafts to be absorbed, it has several times occurred that after hemorrhage into them, either from placing them too roughly upon the granulating surface or by attempts at the removal of one of them, after skin had formed over them, a circumscribed ulcer would form at the site, which would close immediately after the removal of the bit of unabsorbed sponge. The explanation of this doubtless is that the extravasated blood, coagulating within the meshes of the sponge, prevents vascular and cellular infiltration of the piece, the *sine qua non* of its absorption and desired encouragement to cicatrization. Of course impurities of any kind would have a much worse effect, hence great care should be observed in preparing and placing the grafts.

So far I have grafted seven cases. Not selected for any particularly favorable feature in the ulcers, but all average, indolent ulcers, resulting from severe injuries and arrived at that state of chronicity where nature seems to wait in patient expectation of the surgeon, by art, rejuvenating tissues

she has worn old and callous in her attempts at repair.

As the largest ulcer grafted and as affording the most typical illustration of the action of sponge grafting in small bits, I will give the fifth case in my order of grafting somewhat in detail, and take it *first* in my present report. I shall then give the others briefly with only the main points noted.

CASE I.—Ulcer of the antero-internal aspect of the thigh resulting from a very severe lacerato-contused wound of the thigh and abdomen. This ulcer was grafted first July 30th, at which time it measured 10x6½ inches. Ten grafts were applied ¾ inch from the margin of the ulcer. They were applied only on the sides, not at the ends or in the centre. August 2d, dressing removed for the first time. All the grafts firmly adherent. The lymph-tracts and bloodvessels distinctly seen entering the sponge-bits on every side. The raised hard edges of the ulcer disappeared, and on both sides, the whole extent, a flat faint blue edge sending numerous little capes into the sea of granulation. The ulcer measures 10x4½ inches. August 10th, ulcer measures 10x3 inches, most of the grafts already covered by skin, the others entirely embedded in the granulations. August 12th, ulcer measures 9½x3 inches, regrafted with 12 grafts placed as before. August 15th, first dressing after last grafting, ulcer measures 9½x2¾ inches. August 18th, measures 9½x2½ inches. August 22d, measures 9½x2¼ inches. Since July 30th (3 weeks) the ulcer had contracted ½ inch length-wise and 4¼ inches laterally. It will be observed that at both graftings, the grafts were placed on the sides of the ulcer and the contraction or cicatrization of the ulcer had been principally lateral. At this time, August 22d, again grafted, using 16 pieces, placing some at either end, and in the centre as well as on the sides. August 25th, first dressing, ulcer measured 9x2¼ inches. September 1st, only 10 pieces of sponge can be located; two distinct islands of skin beginning. A fourth grafting was done September 8th. October 8th, patient discharged with an ulcer ½x4 inches, to be treated in out-door department. At present time, October 25th, ulcer about entirely cicatrized.

CASE II.—Very indolent ulcer after lacerated wound of ulnar side of the wrist and hand, involving in the hand all the tissues of the hypothenar eminence down to the periosteum of the metacarpal bone of the little finger. Ulcer at time of grafting, May 21st, measured 3½x2½ inches: all "took." Patient discharged, July 11th, cured.

CASE III.—Ulcer of the dorsum of the foot, after severe lacerato-contused wound of the toes and foot, also very chronic. June 1, measured 3x3 inches, 8 grafts, all took. Discharged July 29th, cured.

CASE IV.—Large ulcer of the postero-internal aspect of the thigh, subsequent upon severe contused wound. June 1st, measured 4x2 inches; 12 grafts, 4 of these were pulled off by very careless dressing on the third day afterward, but the copious hemorrhage and the depressions left in the surface of the granulations showed that they were firmly ured 3x1 inches. Regrafted, 10 grafts used. Discharged June 29th, with an ulcer measuring ¾x½ inch perhaps. Attended the out-door department and in two weeks entirely cured.

CASE V.—A very irregular ulcer, reaching from malleolus to malleolus posteriorly and upwards to about middle of the lower third of the leg on either side; also downwards to plantar margin of the heel, resulting from severe burn. This grafted twice. First, May 29th, 22 grafts; and second, June 10th, 18 grafts. All took. June 30th, ulcer entirely healed. At this time however, a retrograde action began, and in a week the cicatrix had broken down into a characteristically specific ulcer. The points of skin formed over the sponge grafts were the last to yield, and their sites the first to begin healthy reaction under specific treatment.

CASE VI.—Very similar to fifth. Very irregular ulcer of sole, heel, and posterior surface of ankle, extending to middle of the lower third of the leg. Grafted twice, first, August 11th, 20 grafts; second, August 31st, 28 grafts applied; all took at both graftings. At present, October 25th, notwithstanding various injuries to granulations in attempts at moving the foot and walking, patient is doing well, and will be discharged in a few days.

CASE VII.—A very indolent ulcer over the posterior surface of the elbow-joint, after severe laceration of the elbow-joint and posterior surface of the arm. Measured, August 31th, 3½x3 inches. Applied 10 grafts, all took. October 18, ulcer healed.

The *modus operandi* of sponge grafting appears threefold. First. The grafts afford support and lodgement for the new bloodvessels forming the granulations. Second. They encourage by direct protection, and a stimulation difficult to understand, the genesis of the large nucleated cells and so-called "lymph bands" into distinct centres of cicatrization. Third. Their chief action is to stimulate to a remarkable degree the activity of the marginal cicatrization.

The first proposition seems obvious and requires no enlargement.

The second requires for a proper appreciation a cursory glance at the by-laws—so to speak—of cicatrization. Granulations are loops of new formed bloodvessels with coverings of mucoid or embryonic tissues and a few intercellular fibrillæ. From the bloodvessels there is a constant emigration of white blood corpuscles, also a rapid endogenous multiplication of the mucoid cells; to this activity and the marginal contractions must every ulcer owe its final integrity. Unprotected, under ordinary circumstances, a large number of these cells die and are swept away as pus from the surface of the ulcer; if, however, a porous animal substance, rendered perfectly unirritating, be interposed, it will furnish lodgement, in the aggregate, for a large number of the cells and protect them—while being itself absorbed—during their higher development. This office I believe the sponge grafts to perform. Small bits are preferable on the flat surface of an ulcer to one large piece cut to cover the whole area of the sore, because the large piece is much longer of ab-

ably in place until firmly adherent, and because in many instances where an ulcer is so irritable that it will not submit to a *large* piece of—*in itself*—unirritating animal substance without rebellion, very small pieces of the same disseminated over its surface are retained and readily absorbed. It is rare, moreover, to find an indolent ulcer of large extent with "healthy granulations" over its entire surface; by using small bits of sponge it is possible to take advantage of what favorable area there may be, and thus encourage cicatrization in a part while waiting for the rest to get into proper condition. The stimulation by central cicatrization is difficult of explanation. I hold the orthodox principle of "like generating like" in nature. I cannot contend, therefore, that a bit of the skeleton of a protozoan would proliferate into epithelial cells, nor would I dare insinuate that the mucoid tissue and neophytes grounded upon, and proceeding from the fibroid group of connective tissue would develop into squamous epithelium. Still I must assert from direct and repeated observation, that I have seen cicatrization beginning around and over a sponge graft isolated entirely from everything but granulations—these granulations having originated from a basis substance entirely destitute of epithelium. So far I have not been able to explain this phenomenon clearly, and must leave it for further investigation.

The third and last is a very marked feature in sponge grafting. One of the very first effects observed in the ulcer is the renewed activity of its edges. I have repeatedly noted a contraction of ½ inch on the third day after grafting. This is probably due to the stimulation of the largely increased number of capillaries formed in the ulcer by the assistance of the sponge supports, and the supernutrition thus insured, epithelial proliferations keeping pace with mucoid. Reverdin noted as one of the chief benefits of skin grafting, the stimulating action it exercised on the margin of the ulcer, one which every surgeon since his time has awaited anxiously as the sure harbinger of rapid cicatrization. This effect is observed usually *after* the skin islands have formed in the skin graft method, whereas in sponge grafting it appears almost immediately, and once started it never ceases until the ulcer is healed.

The ulcers noted in this paper were all results of deep wounds and not only such as are ordinarily very slow and tedious in healing, but are commonly followed by serious contractions. Yet in no case has there, so far, resulted any notable distortion. The cicatrices were firm, but aside from slight depressions after the deep wounds, no deformity has occurred, though all the ulcers were on extremities. The two, of the hand and foot respectively (Cases II. and III.) left not only no contraction, but also no interference with motion.

A comparison of the two methods results in the following conclusions, to wit:

1st. Sponge grafts are available when skin cannot be obtained. They cause no pain in preparing them, nor any annoying little wounds as additional tax on the healing powers of the patient. They do not subject the recipient patient to the danger of inoculation of specific diseases—as skin may do when taken from a cachectic donor.

2d. Sponge grafts take more surely; invariably, when proper care is exercised.

3d. Sponge grafts stimulate marginal activity much earlier and to a much greater degree than skin.

4th. In sponge grafting skin or cicatricial islets are much slower of formation, and not as sure as after skin grafting.

5th. Healing seems equally, if not more rapid with sponge grafts than with skin.

6th. Resulting cicatrices are equally good and contractions equally prevented.

POISONING BY TEN GRAINS SULPHATE OF MORPHIA TREATED BY SULPHATE OF ATROPIA; RECOVERY.

BY E. STUVER, B.Sc., M.D.
OF RAWLINS, WYOMING TERRITORY.

MRS. B., æt. 21 years, married two years, has had one child which was delivered piecemeal, and is now about six or seven months advanced in her second pregnancy. She is of a melancholic temperament, and twice previously took opium with a suicidal intent—once during her former pregnancy. Has not been enjoying very good health recently, and, during the last few days, has been under the care of another physician of the town. On the afternoon of October 24, 1882, this physician injudiciously gave her twenty grains of morphia sulphate in bulk, and some whiskey. During the afternoon she took five or six ounces of whiskey, and about six o'clock in the evening ten grains of morphia. It was soon noticed that she had a peculiar expression of countenance; face somewhat flushed, and eyes bright and sparkling. She soon began to sob hysterically, and her husband, thinking she was merely despondent, tried to soothe her; but she told him it was too late, and that she would not be alive in the morning, at the same time pointing out a bottle of morphia which was subsequently found to contain nine grains of that drug. I was summoned at seven o'clock P.M., and found the patient unconscious and rapidly lapsing into a comatose condition; breathing very irregular, at times superficial, short, quick, and gasping, followed by an interval of from ten to fifteen seconds, during which the respiration was entirely suspended; face flushed, of a livid, cyanotic hue, swollen, and anxious; upper lip largely swollen; eyes injected, and *pupils somewhat contracted, but not nearly so much as they should be to correspond with the gravity of the other symptoms;* she was profoundly unconscious and could not be made to notice or answer questions by slapping, pinching, or in any way. Pulse, about 100.

I immediately gave a hypodermic injection of one-thirty-fifth grain of sulphate of atropia in aqueous solution. For about fifteen or twenty minutes the symptoms continued to increase in intensity, the breathing being very labored and shallow, and the pulse about 150 per minute. When the physiological antagonism of the atropia began to manifest itself, however, a remarkable change took place; the pulse diminished in frequency and became fuller;

the respiration became quite regular, fuller and natural in rhythm; the pupils dilated widely, and the countenance assumed a more healthful appearance. This favorable condition lasted from twenty to thirty minutes, when the pupils began to contract quite rapidly; irregular, shallow, and labored respiration supervened, and the pulse became very frequent. At eight o'clock, or one hour after the first, I gave a second injection of one-fortieth grain of atropia, which, in about fifteen minutes, was followed by the same favorable changes as the first; the breathing became full, deep, and regular; the pulse diminished in frequency, and the condition improved in every respect. At nine o'clock respiration was 16 per minute, pulse about 100, and temperature (Kew) 100° in axilla. About ten o'clock the patient began to notice loud noises, and a little before eleven called for water, of which she drank about an ounce without difficulty. As no unfavorable symptoms supervened, I left the case about eleven o'clock P.M.

October 25, 9 A M.—The patient slept very naturally and comfortably all night, no unfavorable symptoms supervening, and this morning talks quite rationally; has a severe, dull, heavy, frontal and vertical headache, and some nausea, but otherwise feels quite well; no motor or sensory disturbances, except slight numbness in the knees, discoverable; pupils, slightly enlarged.

This case furnishes another illustration of the fact, insisted upon by Prof. Bartholow, in his work on the "Antagonism between Medicines and between Remedies and Diseases," viz., that the condition of the pupil *does not always* furnish a safe criterion by which the gravity of the case can be estimated.

If the above report is instrumental in inciting a more careful study of the antagonism existing between remedies and a careful perusal of such excellent works as that of Prof. Bartholow, above alluded to, it will not have been written in vain.

A CASE OF TRAUMATIC TETANUS; RECOVERY.

BY GEORGE W. LE CATO, M.D.,
OF ACCOMACK COUNTY, VA.

THE following case is reported as another among the comparatively few recoveries from well-developed *traumatic tetanus*:

Tom S., negro, 18 years old, well grown and healthy; wounded at a negro serenade on Sunday night, April 30th. The injury was the result of an accidental discharge of a musket heavily loaded with powder and wad. The muzzle being in close proximity to the patient's right leg, the charge entered the belly of the gastrocnemius muscle, making an irregular, ragged opening three inches in diameter and an inch in depth. The wound was undermined, blackened, and burnt with powder, and contained imbedded fragments of clothing and paper-wad. Separated from it by a bridge of integument was a smaller wound, about an inch in diameter. These were both carefully cleansed, pared with scissors, and dressed with carbolized applications. The case progressed well. The bridge of integument separating the two wounds broke down after a few days, making quite a broad and ugly-looking sore, but there was less suppuration and sloughing than might have been expected.

May 14 (two weeks after the accident).—The patient began to complain of fulness and pain in the chest. Had experienced some stiffness of the jaws for two or three days, which he had attributed to a carious tooth, and of which he had made no complaint. He described the suffering in the chest as a "swelled-up feeling," which rendered him unable to stoop forward, and which he located immediately behind the sternum. Was unable to open the jaws sufficiently to admit the finger. No appreciable stiffness of other muscles, and no spasm. The wound had now filled up to a level with the surrounding surface, and was in all respects healthy. Ordered a purgative, to be followed with 10 grains of Dover's powder.

15th.—Did not sleep well during the night; had been disturbed by twitchings and startings. The distress behind the sternum had increased and there was evident tonic spasm of the deeper muscles, especially of the right leg. No feverishness, and the appetite fairly good. Ordered 15 grains chloral and 30 grains of bromide of potassium, to be taken every two hours until he slept. The usual dressing of carbolized oil, and laudanum and water to be continued.

16th.—Had rested some after two doses of the anodyne had been given, but was repeatedly awakened by severe "cramps," attended with opisthotonos; the seizures coming on every three or four hours, with milder attacks at shorter intervals. Was irritable and despondent. Ordered one drachm doses of bromide every three hours during the day, and 20 grains of chloral every three hours during the night, until he slept. Concentrated nourishment to be systematically administered, and all the solid food given that could be gotten through the mouth. A poultice was applied to the wound.

17th.—Did not sleep until two doses of the chloral had been given. Was still sluggish from effects of the medicine at 8 A.M. Disease fully developed. All the muscles rigid from tonic contraction, and the abdominal walls as hard as a board. Suffered severely from attacks of clonic spasm, accompanied with violent opisthotonos, and attended with loud cries. These were especially induced by all efforts of movement, attempts to speak, or even being spoken to. Tincture of physostigma in 15 drop doses was now added to the bromide, and the medicine continued every three hours during the day; a half drachm of chloral to be given at bed time, and repeated if necessary. A special attendant was detailed to superintend the feeding.

18th, 19th, 20th.—Had taken each day a half ounce of bromide, and a drachm of tincture of physostigma, with 30 to 60 grains of chloral during the night; and been well fed with milk, soups, oysters, and boiled fish. Condition of the muscles apparently slightly improved, but the paroxysms as frequent and severe as ever. Had suffered attacks of spasm about every half hour during the night, but generally dozed in the interval. Constantly bathed

in profuse perspiration; pulse 65 to 75, but extremely rapid and irregular during pain. Had become an object of neighborhood curiosity, and was evidently worried by the presence of visitors; quarrelled constantly with the attendants, and had grown peevish and unreasonable. Considerable difficulty in voiding the urine, and was annoyed by a collection of gas in the bowel that evidently added to the suffering. Continued the treatment, and ordered an ounce of castor oil in calamus infusion, to be repeated as occasion demanded.

21st.—Experienced considerable difficulty in moving the bowels, but sundry doses of castor oil and epsom salts, followed with large enemas of warm water, brought away some hardened feces, with obvious good effects. Pulse feeble and slow, with tendency towards delirium. Considerable embarrassment of respiration during spasm.

22d, 23d, 24th.—Usual treatment steadily continued. Wound suppurating freely. Paroxysms less violent, but patient feverish, with inclination to talk at random. Had become suspicious of his mother and grandmother. The bowels were again moved, with some difficulty, and with some apparently good results. Slept at intervals during the day and night, and took large quantities of nourishment daily.

25th, 26th, 27th.—Tonic spasm of muscles evidently subsiding, and paroxysms less frequent and severe. Had been placed in an easy chair for an hour every day, at his own request, and apparently suffered less in that position. Notable improvement in the facial expression, the *risus sardonicus* having been well marked. Treatment continued as before.

From this time the case began to progress towards recovery. The bromide and physostigma were continued in gradually decreasing doses, and finally withdrawn. The chloral was continued at night for several days afterwards, in order to procure rest from annoying cramps that prevented sleep. A notable rise in the frequency of the pulse occurred, when the daily doses had been withdrawn, ranging considerably over 100 after convalescence was fully established. Professional visits were discontinued after June 1, a little over two weeks from the beginning of the attack.

In the present state of our knowledge of the pathology and essential nature of tetanus, it may perhaps be safely classed among the so-called self-limited diseases. Though death may occur at any stage from spasm, it doubtless results in the vast majority of cases from exhaustion. The above treatment was designed to answer, as far as possible, the plain indications: first, to control, as far as the resources of medicine would serve, the violence and danger of the paroxysms; second, to support the strength by securing rest and nourishment. Experience proves that where patients can be kept alive for ten days, there may be a reasonable prospect of recovery. It is a doubtful question how far the muscles of deglutition and respiration may be made available without the employment of adequate measures to control the element of spasm. What valuable aid may be derived from the three agents so persistently employed in the above case, the result seems to indicate; and it is fair to presume that a persevering system of *feeding*, not of liquids alone, but suitable solids, may do much towards assisting the patient over the period of greatest danger.

More than half of a pound of bromide of potassium was administered during the attack, and nearly two ounces of tincture of calabar bean!

MEDICAL PROGRESS.

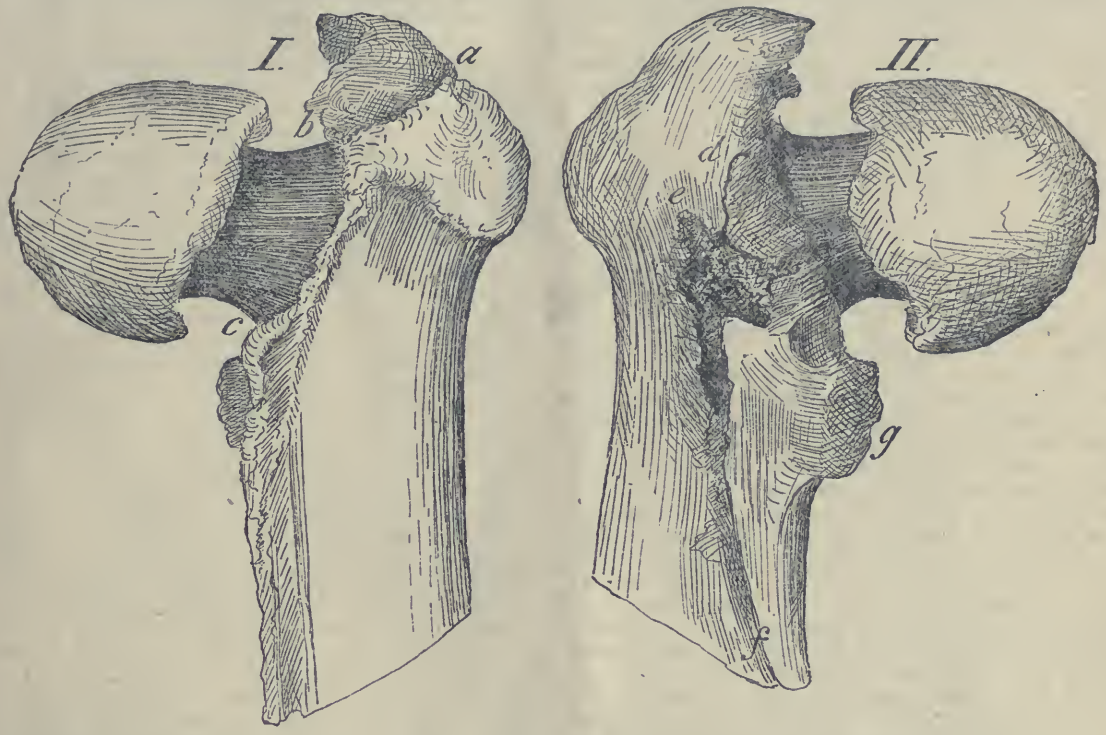
OCCULT CASES OF PYÆMIA.—DR. P. K. PEL (*Zeit. f. klin. Med.*, iv., 1882) gives an analysis of certain cases of obscure febrile disease, in which a source of pyæmic infection was only discovered on post-mortem examination. In commenting on the importance in diagnosis of remembering such a possibility, he remarks as follows: A previously healthy person is attacked with a quotidian pseudo-intermittent fever, associated with swollen spleen and disturbed digestion. No local cause of the (fever such as empyema, tuberculosis, etc.) can be made out by physical examination. The usual febrifuge medicines, given in sufficient quantity and in good time, have no abiding effect. In such a case the diagnosis will lie between—(1) occult or cryptogenic pyæmia; this is most likely when the feverish attacks are very severe; it is not excluded by the appearance of labial herpes: (2) ulcerative edocarditis; the physical signs will serve to confirm this: (3) irregular typhoid: (4) syphilis, even though for the time no other signs can be discovered.—*Practitioner*, Nov. 1882.

IMPACTED FRACTURE OF THE NECK OF THE FEMUR, WITH INVERSION OF THE FOOT.—DR. W. J. CONKLIN, of Dayton, Ohio, reports in the *Columbus Medical Journal* for November, 1882, the case of a large and fleshy but feeble woman, who, on the night of July 5, 1882, fell and injured her left hip. As nearly as could be ascertained, she fell backward and to the left, striking upon the great trochanter. She was unable to move without assistance, but under the impression that it was only a bruise, domestic remedies were applied for a few days after the accident.

When seen, she was in bed with the limb slightly flexed, rotated inwards, so that the patella faced the opposite thigh, and shortened to the extent of one inch. The position of the limb at once suggested a dislocation upon the dorsum ilii. A careful examination, however, showed that the head of the bone clearly rotated in the acetabulum, and that the trochanter moved with it. The left trochanter was distinctly nearer the anterior superior spinous process of the ilium than the right. Pain was caused by pressure over the trochanteric region, which seemed somewhat thicker than on the opposite side. Gentle traction had no effect in overcoming the shortening; moderate flexion gave but little pain. Crepitus was not obtained. An impacted fracture of the neck of the femur was diagnosed, and all manipulative efforts discontinued. She lingered for four weeks after the accident and finally died from exhaustion. The inversion of the foot remained constant during the progress of the case.

The *post-mortem* examination showed that, as is usual in impacted fractures of the neck of the femur, the line of separation at the base corresponds with the anterior and posterior intertrochanteric ridges. In the specimen the whole neck is strongly driven into the cancellated tissue of the trochanteric fragment, and forms somewhat less than a right angle with the shaft. The principal fracture on the anterior surface follows the intertrochanteric line to its termination in the linea aspera (*b*)

about one inch and a half below the lesser trochanter; the neck is driven in so as to leave a fissure, about one-quarter of an inch in width, between it and the anterior wall. A small fissure (*b a*) begins immediately above the tubercle and extends almost horizontally across the greater trochanter for a distance of one inch and a quarter. The principal fracture on the posterior surface corresponds with the posterior intertrochanteric line. The lesser trochanter is broken off and twisted inwards and forwards, evidently by the force of the impaction; without any injurious consequences. The blood of the general circulation was taken from the tip of the finger. In each method every precaution was taken to avoid the accidental introduction of organisms. The examination, in this way, of fifteen patients gave the following result. At the height of the disease the blood of the general circulation contains micro-organisms both isolated and grouped. These consist, almost exclusively, of spherical bodies, which have a delicate contour, appear to be homogeneous, and are analogous to



the fracture communicates with that on the anterior surface. The tilting forward of this fragment leaves an irregular gap (*e*) of more than an inch, at its greatest width, through which the impacted neck can be seen approaching the posterior surface and almost reaching the outer wall of the shaft. A narrow fissure runs (*d*) from the upper margin of this gap along the great trochanter. The head of the femur is somewhat roughened, and an irregular collar of bone projects from the greater portion of the corona, evidently the result of chronic arthritis.

When the specimen was placed in the hands of the artist, the fact that the impaction had been partially released was unfortunately overlooked, and hence the drawings represent the neck considerably longer, and the head less depressed than in the original.

Examples of this accident are of very infrequent occurrence. Profs. R. W. Smith, Bigelow, and Hamilton, have each met with but one case.

THE ORGANISMS OF TYPHOID.—MARAGLIANO, of Genoa, has published, in the *Centralblatt für die Med. Wissenschaften*, an important note on the uniform occurrence of organisms in the blood of patients suffering from typhoid. He has found them in the blood of the spleen as well as in that of the general circulation. The blood was obtained by means of a hypodermic syringe, the needle of which was passed through the abdominal wall into the substance of the spleen. Dr. Sciamano of Rome first showed that blood may be thus obtained from the substance of the spleen during life micrococci. Some of them are mobile. Similar organisms, again, were seen in the blood of the spleen, and in it, too, were others, rod shaped, also with delicate outlines, perfectly corresponding to those described by Eberth and Klebs. During convalescence these micro-organisms lessen in number in both the splenic and systemic blood. When quinine was given to the patient in large doses the organisms either disappeared from the blood, or were present in it only in small number. The blood from both the finger and the spleen was treated by the method of fractional culture, and a large number of rods were then obtained, similar to those seen in the fresh blood except that some of them were of greater length. The presence of such organisms in the blood of the spleen after death had been previously established by Sokoloff and Fischel, but Maragliano is the first who has demonstrated their presence in the splenic blood during life. He avoids the expression of any opinion as to their relation to the disease.—*Lancet*, October 28, 1882.

PYROGALLIC ACID IN THE TREATMENT OF VENEREAL ULCERS.—ANDRIEU (*Thèse de Paris*, 1881) believes the leading advantages possessed by pyrogallic acid in the treatment of chancres consists in the promptitude and certainty of its action, which involves no danger of injury to surrounding parts, and its complete destruction of the virus.

Slightly caustic, and at the same time astringent in its properties, it is superior to nitrate of silver on account of the profound alteration it effects in the substance of

the sore; and to other similar agents, in that it may be applied at any period, whatever may be the age or malignity of the lesion.

The specificity (if we may use the term), as well as the greater celerity of its action on the poison of the disease, render it preferable to iodoform, whose penetrating and disagreeable odor both annoys the patient and betrays the nature of his malady.

Iodoform, it is true, exerts an anæsthetic influence which is sometimes very desirable, but this is not, in every instance, to be relied on, while the pain produced by pyrogallic acid is not severe enough to constitute an obstacle to its use, and, moreover, can always be allayed by such means as the application of chloral compresses, or the subcutaneous injection of morphia.

The only precaution to be observed in the employment of the acid, is not to combine it with soap or any other alkaline substance, as by these we know that it is readily decomposed.—*Journal of Cutaneous and Venereal Diseases*, November, 1882.

PARALYSIS PRODUCED BY INJECTIONS OF ETHER.—DR. ARNOZAN (*Journ. de Méd. de Bordeaux*, 1882) has employed in several cases of variola the method of subcutaneous injections of ether, recommended by Dr. Ducastel (see MEDICAL NEWS p. 290). He found, however that when the injections were allowed to penetrate the muscles that a local paralysis was produced, with suppression of their faradic excitability, but with an increased excitability on galvanic stimulation, and that the response to the faradic current only appeared when the voluntary motor power was regained. The paralysis disappeared spontaneously in time. Cure was much accelerated by the use of the constant current.—*Archives Générales de Médecine*, November, 1882.

CASE OF MEMBRANOUS CYSTITIS.—At the meeting of the Cambridge Medical Society, on October 6th, MR. T. LUCAS produced a specimen from the bladder of a woman, aged 28, whom he had attended for this condition. On the ninth day after her confinement she had pain over the hypogastric region, and retention of urine. In a few days she had feverish symptoms, a temperature of 103°, and pain in the left groin, followed by swelling of the left thigh and leg. The use of the catheter was required for twelve days, after which time the leg was well. The urine contained mucus and albumen. Ten days later there was complete and sudden retention of urine, and on passing the catheter an obstruction was met with, which proved to be a piece of membrane, blocking the urethra. This was withdrawn in pieces and then a quantity of ropy urine escaped through the catheter. A few days later, a piece of membrane, about six inches by four, was removed, and subsequently another piece, ten by twelve inches, came away. Ten days later, the woman had entirely recovered. The membrane consisted of a fibrillated network, in the meshes of which were enclosed leucocytes, granular matter, and crystals of phosphate of lime, and seemed to be a cast of the mucous surface of the bladder. Mr. Lucas considered the case interesting from its rarity, and as indicating the manner in which calculous deposits might occur in the bladder. Such cases were more frequent in females, and might be of a croupous nature, and caused by a septicæmic condition, similar to that giving rise to phlegmasia dolens, and affecting the vitality of the epithelium, and thus causing cystitis. He mentioned a case of Liston's in which the mucous membrane of the bladder was removed entire, a sac six inches by four, as a result of injury.

DR. HUMPHRY said he had, in the case of a young woman, dilated the urethra with his finger, and removed a large amount of mucous membrane, covered with phosphatic deposit, and observed that the mucous membrane of the bladder had hardly any secretion, and very little glandular substance. In cases where the whole mucous membrane sloughed off, it seemed due to a process called by Leuchars necrosis of the membrane—*British Medical Journal*, November 4, 1882.

CASE OF SO CALLED IMPERFORATE HYMEN.—At the meeting of the Obstetrical Society of London, DR. MATTHEWS DUNCAN read a paper with this title. He was induced to relate the case by three circumstances. 1. There was a remarkable absence of any kind of suffering during nearly the whole time of the development of the disease. The patient had never menstruated nor suffered from any uneasiness in connection with that function until eight months before admission, when she was told by a medical man that she had a lump in the lower belly. Since then she had suffered from irregular achings. The author thought the probable explanation of this was that the uterine body was not distended, for facts showed that dilatation of the uterine body was more difficult and painful than dilatation of the vagina and uterine cervix. 2. The case illustrated the treatment without any injections, which had been the subject of remarks at a recent meeting of the Society. An incision was made by Paquelin's cautery knife. About twenty-five ounces of the usual treacly fluid escaped, about twenty ounces on the following day, and the last of it on the fifth day, in all about fifty ounces. At no time had it any fetor. No hypogastric pressure or interference with the flow was permitted. A piece of carbolized lint was put to the vulva. The patient made an uninterrupted recovery. He thought the risk of peritonitis was increased by the washing out sometimes practised. He thought the cautery knife was preferable to any other mode of making the incision, because its wound was not an absorbing surface. 3. The condition of the pudendum, rendering the term "imperforate hymen" erroneous and misleading. The vagina was closed by a membrane upon which the hymen could be seen entire and healthy, and after the operation the hymen could be seen to have its normal position and relations. He had made the same observation in other cases, and he had seen the hymen present when vagina and uterus were both absent. On these grounds he regarded the view of M. Budin (that the hymen was nothing but the anterior extremity of the vagina) as incorrect.—*Lancet*, Oct. 28, 1882.

ON A NEW METHOD OF AMPUTATION OF THE UPPER EXTREMITY.—At a meeting of the Académie des Sciences, M. Joselin presented a note by M. DESPRÈS, on a new method of amputation of the upper extremity. For a case of osteosarcoma of the scapula, M. Despiès performed with success "amputation of the shoulder," that is, entire removal of the arm, scapula, and part of the clavicle. His method of operating was as follows: 1. He tied the subclavian artery, external to the scalenus muscle, by a double ligature to avoid secondary hemorrhage. 2. He made an incision *en raquette*, commencing at the centre of the space separating the eminence of the spine of the vertebræ, at the internal border of the scapula, and at a level with its spine, and following its dorsum, turning round the salient portion of the shoulder and passing under the axilla as far as its centre, and afterwards rejoining the original incision at its starting point. 3. He dissected a superior flap without interfering with the incision for the ligature of the vessel. 4 He divided the clavicle as near as possible to its middle. 5. He tied the axillary vein. 6. The scapula was detached after division of the pectoralis minor and dorsi latissimus, and then dividing the muscles inserted into the scapula. The suprascapular artery

should be tied if necessary, and the wound brought together by sutures. The dangers of this operation consist in, 1, the loss of blood; 2, the possibility of the entrance of air into the axillary vein; but they are not necessarily mortal. One complication occurred—the extremity of the clavicle perforated the skin; but M. Desprès thinks that it is better to have such a condition than to remove the entire collar-bone, and that this portion of the clavicle preserved covers in the superior aspect of the thoracic. The operation, he thinks, is of value in cancer of the scapula, and less formidable than removal of the scapula, leaving the arm, and may be well applied to cases of white swelling of the shoulder involving the scapula. It would seem very practicable in patients below twenty-eight years of age.—*British Medical Journal*, November 4, 1882.

TUBERCULAR SYNOVITIS OF TENDONS.—M. TERRIER made a communication on this subject at the meeting of the Société de Chirurgie held Oct. 25, 1882. This affection is extremely rare. The first description was by M. Lancereaux some time after M. Débove had found tubercles in a case of synovitis of the carpus; more recently it has been described by M. Bouilly and Prof. Trélat. M. Terrier reports three new cases, in two of which a histological examination was made. Giant cells were found in a mass of granulations formed of embryonal cells, and, at certain points, obliteration of the vessels, but no caseous nodes. Three different types of this disease may occur: the classic tubercular synovitis as described by Lancereaux, Bouilly, and Trélat; a form in which the fungosities are preceded by nodes which rapidly ulcerate; and a third type analogous to the acute tuberculosis of articulations, where the symptoms are those of acute synovitis with effusion. Its diagnosis is difficult. It can be primarily and essentially local, or an episode of a general infection: the prognosis and treatment will vary as either of these conditions exist.—*Le Progrès Méd.*, Oct. 28, 1882.

A NEW TREATMENT OF THE LACHRYMAL PASSAGES BY A DILATOR.—GALEZOWSKI (*Recueil d'Ophthal.*, August, 1882) has for six months practised a mode of rapid and forcible dilatation of the nasal duct without scarification of its walls, which he believes will replace all other modes of enlarging the duct. The instrument employed is a dilator, the blades of which, when closed, form a smooth, round probe, equal in thickness to Bowman's No. 4. When the blades are together the handles are separate. The closed blades are passed into the duct like an ordinary probe. The handles are then pressed together, and the blades in separating produce an effect equal to that of Couper's largest probe; at the same moment the instrument is withdrawn.

The pain, though sharp, is of short duration, and hardly a drop of blood is lost. Ordinarily there is no inflammatory reaction. If the dilatation is practised on inflamed and suppurating tissues, poultices are applied for a few hours afterwards.

A fine probe, No. 3 or 4, is passed on the third or fourth day, to determine whether the duct is free from obstruction, and this is followed by a No. 10 or 12, which is usually introduced without difficulty and with little pain.

By this method the author has obtained complete cures after other measures, perseveringly employed, have failed. Illustrative cases are cited.—*Ophthalmic Review*, November, 1882.

THE PATHOLOGY AND TREATMENT OF DIABETES.—At a clinical lecture at the Hôpital de la Pitié, PROF. LASÈGUE made some very interesting remarks on the pathology and treatment of diabetes. He divides diabetic patients into two classes: fat and lean, according as they may be found in either of these conditions. He also divides them into small and great diabetics, according to the quantity of the sugar which their urine may contain. The patient that excretes twenty grammes of sugar a day may be classed among the former; those who pass more than thirty or forty belong to the second class. Professor Lasègue attaches great importance to this division, for as the small diabetic patient never becomes a great one, each class retains its peculiar character; from which it may be concluded that a patient who presents great irregularities in the quantity of sugar he excretes, and appears to pass from one class to the other, is affected more with accidental or casual diabetes than with the true affection. A third class of diabetic patients is what Professor Lasègue calls "les diabétiques fixés," and these may be found among the two former classes. In this class of cases the quantity of sugar excreted varies only by a few grammes, whatsoever the treatment employed, or the diet adopted, but this should not be considered of much importance in a prognostic point of view, the quantity of sugar not being a fair criterion of the gravity of the disease; for although the proportion of sugar in the urine may remain stationary, the extent of the general disorder of the system may still be very considerable. This, however, does not apply to patients who pass 200 or 300 grammes of sugar in the twenty-four hours; these cases must be considered exceptional, and always of some gravity. M. Lasègue establishes two other forms of diabetes, which he designates the remittent and intermittent; in the first case the quantity of sugar was considerably reduced; in the second the sugar disappears, sometimes even completely, at certain periods; and although these states of remission or intermission may be considered more favorable than the other forms, yet patients of this category become cachectic, as patients of the other classes almost invariably do. This state, according to M. Lasègue, would constitute the principal indication of treatment; but he does not approve of the severe restrictions generally placed upon the diet and regimen of diabetic patients. He allows them to continue their usual mode of living, not even depriving them of farinaceous substances, or the use in moderation of sugar, water, or wine. As for gluten bread, so much prescribed for these cases, M. Lasègue condemns it *in toto* as not only being worthless, but it ends by disgusting the patient, takes away his appetite, and so hastens the cachectic state, which it is the very object of the physician to avert by all the means in his power.—*Lancet*, October 28, 1882.

THE TREATMENT OF EFFUSION INTO JOINTS.—PROF. VOLKMANN observes (*Centralblatt f. Chirurgie*, August 19, 1882) that in chronic effusion into the joints, he has several hundred times punctured and washed out the cavity with a solution of carbolic acid of from three to five per cent. without ever meeting with any accident or disturbance. As a general rule, from ten to fifteen syringes full, each capable of holding forty-five ccm., had to be employed, and the fluid allowed to run away, before it was discharged clear; the synovial fluid, which the added carbolic acid speedily renders turbid, was then known to be entirely removed, and the joint thoroughly washed. In order that the carbolic acid might exert its influence on every part of the surface of the capsule, the joint was then moderately filled by the injection of from one to three syringes full, and then submitted for a short time to movements of flexion and extension. A larger quantity of the solution than this was never left in the joint. No symptoms of carbolic intoxication were ever observed. After the washing-

out was finished, the limb was always surrounded by a Lister dressing, and kept immovable for some time on a splint. When the effusion was not of too old a date, recovery has always followed a single puncture and washing-out, although, as a rule, firm bandaging is required for the prevention of relapse, for diminishing the thickening of the capsule, etc. In bad cases, with great distention of the capsule and ligaments, due to large and old effusions, the puncture and washing-out have to be repeated two, three, and even four times, at intervals of several weeks, before the capsule contracts sufficiently. Iodine injections, which Prof. Volkmann formerly employed frequently, he has now discontinued. They have no advantage, and occasionally give rise to suppuration of the joint. In the worst cases with great distention and thickening of the capsule, villous growths, large fibrinous coagula, dropsy, loose bodies, or *gonitis fibrinosa* without fluid exudation, Prof. Volkmann always makes a double incision into the joint and introduces two short drainage-tubes, which, after carefully washing out the joint, are left in as long as any secretions issue through them. He is unable to say how often he has performed this operation, by far the most frequently executed on the knee, but certainly more than a hundred times. Even in these cases only disturbances of a very slight nature were met with, although bad cases were often treated. The general conclusion, therefore, is that both puncturing and washing-out the joint, and the double incision and drainage with the aid of antiseptics, may be declared to be operations unattended with danger and followed by satisfactory results. How thoroughly Prof. Volkmann has been convinced of this may be inferred from the fact that for a series of years he allowed Prof. Rancke to attach a manometer to the trocar, in order to institute experiments on the intra-articular pressure in the living man. None of these experiments did the slightest harm to the persons on whom they were performed.—*Practitioner*, November, 1882.

ERYSIPELATOUS ORGANISMS.—In several patients suffering from erysipelas FEHLEISON has found micrococci to be constantly present in the lymphatic vessels of the skin in the parts invaded by the inflammation. He has endeavored to ascertain whether these organisms can be regarded as the veritable cause of the disease. The method of his proceeding (according to an abstract which has appeared in the *Gazette Médicale de Paris*) was to excise minute fragments of skin, having first washed the surface with ether and with a solution of corrosive sublimate. These fragments were afterwards placed in gelatine prepared after the method of Koch. The micrococci rapidly grow, forming an abundant vegetation around the small fragments. By means of a platinum needle the mould was transplanted from one spot to another on the surface of the gelatine, and a thin membrane formed around each point of inoculation. The colonies of micrococci grow slowly, and at the usual temperature of the air their development soon became arrested. The organism appeared identical in appearance with those seen in the fresh preparations, except that in the gelatine the micro-organism formed longer chains. Fehleison tested the virulence of the fourth generation of these organisms by an operation which most of our readers will probably agree with us in considering wholly unjustifiable. He inoculated the germs in the skin of the gluteal region of a woman, aged fifty-eight, suffering from multiple fibro-sarcomata of the skin. The inoculation was made by five punctures with a lancet. Up to that time the temperature of the patient was normal. On the evening of the inoculation the temperature was 37.7° C., but the next day the woman had a slight rigor, headache came on in the course of the day, and in the evening the temperature was 38.8° (101° F.). On the morning of the third day it was 37.2°, and in the evening 37.8°. On the fourth day another rigor occurred, and there was found on the left buttock an erythematous patch, prominent and circumscribed, having all the characteristics of erysipelas, and during the day it spread considerably in extent. The temperature was 40.4° (104.7° F.) in the morning, and 40.6° in the evening. On the fifth and sixth days the temperature was 41° C. (105.8° F.), and on the latter the woman fell into a state of collapse, from which she was roused by a subcutaneous injection of ether. On the seventh day the erysipelas occupied an area of a square foot. It remained stationary during the next three days, the temperature oscillating between 39.2° (102.6° F.) and 40.6° (105° F.); then the erythematous patch began to subside, but the temperature continued raised, and even on the thirteenth day was 40.0° (104° F.), but after the fifteenth day it was normal. As a consequence the infiltrations of the skin seemed to have slightly lessened. The author remarks that erysipelas can readily be communicated to rabbits, especially if the inoculation is made upon the ear. We echo the hope expressed by the editor of the *Gazette Médicale*, that those who endeavor to corroborate the observation, if rabbits do not suffice for their needs, will have the courage to operate on themselves.—*Lancet*, November 4, 1882.

TREATMENT OF CERTAIN SKIN DISEASES BY LINEAR SCARIFICATIONS.—AUBE (*Thèse de Paris*, 1881) concludes:

1. Linear scarifications constitute the best mode of treatment in tubercular lupus.

They are to be preferred to scraping, either alone or in conjunction with the former.

In erythematous lupus, scarifications act with less promptitude, and in acneic lupus they are ineffectual unless carried deeply and combined with punctures.

2. Together with this means, internal medication should always be employed.

3. Scarifications are seldom useful in the treatment of vascular nævi; yet it is well to give them a trial in such cases by operating on a small portion of the tumor.

4. They are more serviceable, when combined with epilation, in parasitic sycosis, with abscess of the derma, as also in non-parasitic sycosis (*impetigo sycosiformis*).

5. Greasy seborrhœa, so refractory under other treatment, is amenable to this.

6. In rosacea, scarifications can only be relied on before the hypertrophy has become too far advanced.

7. Notwithstanding apparent counter-indications, this practice has been successfully employed in some cases of keloid.

8. Scarifications probably act in several different ways—by substitution or revulsion, and also by obliterating a certain number of bloodvessels, so as to prolong the life of the healthy tissues, while those already becoming devitalized are disposed of by cutting off, even though but partially, their sources of supply.—*Journal of Cutaneous and Venereal Diseases*, November, 1882.

OZONIZED AIR AS AN ANÆSTHETIC.—PROF. BINZ has just published a second communication on the anæsthetic and hypnotic properties of ozone, but his results are marked by great inconstancy, and are no more encouraging than those first published; in some instances the inhalation of ozonized air soon caused sleep, while in other cases no effect whatever was observed.—*Berliner klin. Woch.*, October 23, 1882.

Cæsarean Section and Ovariotomy without Anæsthetics.—Johnen (*Centralbl. f. Chirurg.*, 1882, Nos. 9 and 20) states that his teacher, Kilian, advised the disuse of anæsthetics during the operation of Cæsarean section, as he considered that great harm was frequently done by the production of vomiting, and that a conscious patient was not only less apt to disturb the surgeon by movements or straining than an anæsthetized one, but might aid him materially during the operation. He further thought that narcosis increased the tendency to subsequent hemorrhage. Johnen has acted on this recommendation, not only in Cæsarean section, but also in ovariotomy, and is so well satisfied that he now regards "narcosis" in Cæsarean section as "always unnecessary and often hurtful." In ovariotomy he considers it should only be induced in certain cases (not described) "where some psychic or somatic peculiarity renders it advisable." Riedel has performed ovariotomy twice, giving only enough chloroform at the beginning of the operation to render the patient insensible to the pain of the incision through the skin. He finds that the subsequent steps of the operation, even the securing and division of the pedicle, cause no pain, and that the patient can talk, drink wine, and move herself freely during the operation if requested to do so. Köenig lately performed ovariotomy on a "very decrepit" woman aged 65, removing a cyst which held "three large bucketfuls" of fluid, and tearing thorough firm adhesions, without anæsthetics. The patient made no complaint except during the first incision and during the introduction of the superficial sutures of the integument. These surgeons claim that the patients who are not anæsthetized are in better condition after the operation than those who are, and recover better.—*Glasgow Medical Journal*, November, 1882.

The Fermentation of Nitrates.—The researches of Schloesing and Muntz have shown that the formation of nitrates in the soil and in organic liquids is due to the development of ærobic organisms. Certain facts recorded by Boussingault, Schloesing, and others have suggested to MM. Gayon and Dupetit that the opposite process, the reduction of nitrates, may also take place in a similar manner. The results of an investigation which they have made has been communicated by them to the Académie des Sciences of Paris. To street drain water nitrate of potash was added in the proportion of .02 gramme per litre, and then some decomposed urine. The nitrate disappeared gradually, and the liquid became filled with microscopic organisms. Successive cultures of these enabled the experimenters to effect the reduction of one and even two decigrammes of nitrate of potash per litre. By employing decoction of chicken as the basis they were enabled to decompose as much nitrate as amounted to 5 per cent. of the liquid. That the organisms which developed under these circumstances were really the cause of the denitrification was proved by sterilizing the liquid by heat, or by the addition of chloroform, or sulphate of copper, when the nitrate of potash underwent no alteration. The organisms concerned seem to be anærobic; if they were cultivated in a large surface, and in contact with air, either they did not produce the effect at all, or their action was considerably lessened. The temperature most favorable to the process was found to be between 35° and 40° C. The presence of organic matters is absolutely necessary, but all organic substances are not equally suitable. Of those which have been tried, olive oil, and oil of sweet almonds, glycerine, glycol, sugar, alcohols of the fatty series, tartrates, etc., the best results were given by sugar, ordinary alcohol, and propylic alcohol. For instance, three or four drops of the latter, added to a liquid in which the denitrification was suspended, at once renewed the process. The oils became rapidly saponified. Considerable interest attaches to the action of two substances, carbolic acid and salicylic acid. Employed in the proportions usually considered to be antiseptic, and even in still larger quantities, they not only did not interefere with the growth and activity of the organisms, but were themselves destroyed with the nitrate, just as sugar or propylic alcohol would be. The destruction of carbolic acid by organisms has been already observed by Muntz, even when it amounts to several grammes per litre. Thus under favorable circumstances the process of the destruction of nitrates presents all the characters of an energetic fermentation. It is accompanied by a rapid growth of organisms, and an abundant liberation of gas. This gas consists of pure nitrogen, and represents a considerable proportion of that contained in the nitrate. The rest probably forms ammonia. The oxygen forms carbonic acid, which remains combined in the liquid. The influence of the organic matter is thus to cause the products of the fermentation of the nitrate to enter into new combinations. Other nitrates behave in the same manner as the nitrate of potash.—*Lancet*, Nov. 4, 1882.

Bacteria of Ophthalmia Neonatorum.—Dr. Fedor Krause has adopted Koch's method in cultivating the micrococci of ophthalmia neonatorum (*Berl. klin. Woch.*, No. 37). The cultivation from pus succeeded only at a hatching temperature, and in sterilized blood-serum of mutton. The further cultivation of the pure material was found to be possible at the temperature of the room in every favorable kind of food. Pus from the eyes of twelve children was used, and in all these cases a pure cultivation was obtained, after the presence of the characteristic micrococci had been demonstrated in the secretion. In two cases the breeding was continued by successive inoculations up to the forty-second and fiftieth generation. The micrococci are figured like two rolls opposed end to end; they retain their appearance for the most part in cultivation in artificial media, though they may present alterations in size. In pure culture the luxuriating micrococci appear gray and yellowish under a low magnifying power; they grow uncommonly slowly, and spread themselves out in the form of a thin covering away from the point of inoculation towards the sides of the vessel; the surface of the film has a moist appearance. Inoculations performed on the cornea, conjunctiva, and urethra of adult rabbits, on the cornea and conjunctiva of young cats, pigeons, and mice, yielded negative results, whether the material used was pure discharge from the eye or that from a pure breeding. As little result was got by subcutaneous injection into rabbits and mice. But inoculation with stuff from pure cultivation caused in new-born rabbits a purulent ophthalmia, which came on in twenty-four hours, and in one animal led to marked suppuration and finally ulceration of the cornea. In researches on five cases of granular lids, no bacteria were found in excised bits of the mucous membrane, and a negative result was the outcome of cultivation experiments—*i.e.*, to ascertain whether breeding would render the micrococci visible, as there might have been so few as not to have been found by the microscope.—*Medical Times and Gazette*, November 4, 1882.

Cysticerci and Tapeworm.—The coexistence of cysticerci and tæniæ in the same subject at the same time has been very rarely noted. An instance was described by MM. Rathery and Sevestre at a recent meeting of the Société Médicale des Hôpitaux. The existence of the tapeworm (tænia solium) was not suspected until it was found post mortem in the small intestine. The patient died from heart disease. Fif-

teen or sixteen cysts were found in different parts of the body. All were situated in the substance of the muscles. The existence of heart disease, and of hæmaturia shortly before death, had led to a suspicion that some of the cysticerci might be located in the kidneys or heart, but the autopsy showed that all the viscera were free.—*Lancet*, November 4, 1882.

THE HYPNOTIC VALUE OF TANNATE OF CANNABIN.—DR. FRONMÜLLER, of Furth, has been investigating the properties of a preparation of Indian hemp, the tannate of cannabin, which he obtained from Merck, of Darmstadt. The tannate of cannabin is a yellowish-brown powder, insoluble in water or ether, slightly soluble in alcohol, and easily dissolved in water made slightly alkaline. It has a taste like tannin, and a not unpleasant smell. In the distillation of Indian hemp, two volatile oils are developed, cannabin oil and its hydrate. These are rapidly acting irritant poisons. They are said to be removed in the preparation of the tannate. Dr. Fronmüller states that he has used Indian hemp itself for thirty years, and that there has been a steady increase in the strength of the preparations furnished him. Thus, thirty years ago, he began with a dose of eight grains, ten years later he had to reduce it to four, and latterly to two grains. The dose of the present preparation, the tannate, ranges between gr. ii and gr. x, the most frequent dose being gr. v. The drug was used fifty-seven times in hospital, and six times in private practice. The patients consisted of twenty-one men and forty-two women, for the most part between twenty and forty years. Forty of them were suffering from phthisis, the remainder had different diseases, generally of a chronic nature. The common symptom in all cases was insomnia, and it was for its hypnotic effect that the cannabin was given. Good results were obtained in thirty-seven cases out of the sixty-three, and moderately good results in fifteen cases. It was called a good result when quiet and uninterrupted sleep came on within an hour after taking the medicine, the patient awakening with no toxic after-effects. In twelve cases no result was produced. Many of the patients had been taking opium. From the sixty-three trials thus reported, Dr. Fronmüller concludes that *cannabin tannicum* is a very useful hypnotic, powerful without being dangerous, and one which does not disturb the secretions or leave unpleasant toxic after-effects, if given in proper dose.—*Practitioner*, Nov, 1882.

MERCURIAL SALIVATION.—At a recent lecture at the Hotel-Dieu, DR. PANAS (*Gaz. des Hôp.*, No. 9) strongly insisted on the employment of means for the prevention of mercurial stomatitis, which, in his opinion, is no indication of the system being saturated with mercury. It is a complication which greatly impedes treatment when it occurs, and which depends upon an anterior alveolo-gingival stomatitis, and may be always prevented by curing in advance, by local means, the condition of the gums and alveoli. This treatment consists first in the removal of the tartar, and then in the application of substitutive topical substances, the chief of which employed by Dr. Panas are tincture of iodine, and carbolic acid diluted to a twentieth; these substances, to be of use, being introduced to quite the bottom of the alveoli. If the gums are quite healthy, and astringents are applied daily (as tannin, catechu, etc.), they may be kept sound and healthy however long the mercurial treatment is continued; and when patients come in with ulcerated or bleeding gums, and loosened and displaced teeth, this condition of things may be remedied in a few days by the above-mentioned procedure. If such precautions be not taken, the irritating action of the mercury exasperates the stomatitis and brings on salivation. Dr. Panas considers the much-praised chlorate of potash quite inefficacious in salivation, and even capable of doing harm by the irritation it produces.—*Medical Times and Gazette*, November 4, 1882.

SUPRA-CLAVICULAR PSEUDO-LIPOMA AND RHEUMATIC ŒDEMA.—M. POTAIN read a paper with the above title before the Académie de Médecine, at the meeting held October 7, 1882. This paper is a reply to the memoir of Verneuil on supra-clavicular pseudo-lipoma, which was described as being characterized by a swelling in the supra clavicular fossa, which is thus transformed into a prominence slightly above the level of the adjacent parts. M. Potain has been able to confirm Verneuil's descriptions, and gives an account of twenty cases in which the elastic swelling was found; in all of the cases there was a marked rheumatic diathesis. In some cases the swelling exceeded the limits of the space, bounded by clavicle, sterno-mastoid, and trapezius, and in a few instances similar tumors were found in other localities where there is normally found loose cellular connective tissue capable of sustaining deposits of fat. Distinct œdema was also associated with these tumors, and M. Potain believes that both the œdema and morbid increased deposit of fat are caused by the same morbid tendency.—*Le Progrès Médical*, October 21, 1882.
